Remerciements

Si on m'avait dit lorsque je suis revenu en France à l'âge de seize ans, ne sachant ni lire ni écrire le français, que j'écrirai un manuscrit de thèse, je ne l'aurai pas cru. Bien entendu, plus d'une décennie après, la réalisation de ce projet n'a pas été sans difficultés mais l'aide et le soutien de nombreuses personnes que je tiens à remercier, m'ont permis de mener à bien mon projet dans d'excellentes conditions.

Il y a un peu moins de 6 ans, je débarquais à Nice pour m'inscrire dans le parcours recherche. Deux ans après et un Master 2 en poche, j'ai intègré l'équipe *Géochronologie-Géochimie-Pétrologie* (GGP), récemment incorporé avec d'autres pour former l'équipe *Dynamique Orogénique* dans le cadre d'une thèse. Depuis, ayant vécu des moments forts, aussi enthousiasmants que décourageants, et rencontré des personnalités aussi embrasées que rassurantes, j'aimerai remercier tous les gens qui m'ont aidé de quelconque manière et en particulier l'énumération suivante.

Je voudrais tout d'abord témoigner de ma gratitude envers ***Marc SOSSON*** et ***Yann ROLLAND*** qui ont été présents tout au long de ces 3 ans et demi (et plus en comptant la première et deuxième année de Master). Que ce soit sur le terrain, au laboratoire ou en salle de cours, d'un soutien permanent, vous avez su me prodiguer des conseils judicieux et de profiter de vos connaissances, de vos expériences et votre savoir-faire. A l'écoute, vous m'avez néanmoins laissé libre autant sur le plan scientifique que sur le plan organisationnel tout au long de ma thèse. Je vous remercie grandement.

Merci aux membres du jury qui m'ont fait l'honneur d'accepter, de s'intéresser et de juger ce travail. Je tiens donc à remercier ***Yves LAGABRIELLE***, ***Roland OBERHÄNSLI***, ***Andrea ZANCHI***, ***Séphane GUILLOT*** et ***Carole PETIT***.

Ma gratitude va également aux collègues arméniens ***Ara AVAGYAN***, ***Ghazar GALOYAN***, ***Mushegh MKRTCHYAN***, ***Lilit SAHAKYAN*** et ***Sargis VARDANYAN***. Je peux vous assurer qu'en arrivant dans un pays peu connu, un visage familier vaut bien tout l'or du monde. C'est pourquoi par la même occasion, je voudrais remercier ***Gültekin TOPUZ*** et ***Ömer Faruk ÇELIK***, des collègues turcs. Je remercie également ***Carla MÜLLER*** pour sa bonne humeur, ses sourires, sa manie de toujours garder un morceau de pain pour les animaux qu'on croiserait mais surtout pour sa manière de me motiver sur le terrain en fin de journée pour fournir un dernier effort

Je voudrais aussi témoigner de ma gratitude envers ***Thibault DURETZ*** pour sa connaissance en matière de modélisation numérique.

Je remercie ***Claude MERLET*** et ***Bernard BOYER*** de Géosciences Montpellier ainsi que ***Jean-Luc DEVIDAL*** l'Université Blaise Pascal, Clermont-Ferrand pour leur aide lors d'analyses à la microsonde.

Je remercie, à titre posthume, ***Michel MANETTI*** pour la découverte d'artistes, du travail de la pierre, l'aide technique,…et des longues discussions qui ont rendu les heures de divers broyage et de séparation minérale supportables. Je souhaite rajouter ***Sylvain GALLET***, sans qui une grande partie des analyses géochronologiques seraient du domaine du rêve.

Je tiens à remercier ***Gérard GIANNERINI*** et ***Jean-Marc LARDEAUX***. Formidables interlocuteurs, excellent géologues et pédagogues, j'ai apprécié votre volonté de transmettre

vos connaissances de la géologie, toujours dans la bonne humeur. Je n'oublierais jamais les très bons moments passés sur le terrain dans les Alpes, que ce soit lors de « Géotravers» ou en sortie avec les étudiants, ainsi que les innombrables discussions scientifiques et non scientifiques, un grand merci.

Je remercie l'ensemble des membres du laboratoire Géoazur avec qui j'ai pu avoir des discussions tout au long de ces années. Je voudrais remercier l'équipe de direction, en particulier ***Emmanuel TRIC*** et ***Jenny TREVISAN***, pour leur présence et assistance tout au long de ces quatre dernières années. Par la même occasion je tiens à exprimer ma gratitude à tous les gestionnaires que j'ai pu côtoyer (***Véronique LARGE***, ***Magali AUFEUVRE***, ***Reine SAIGHI***, ***Sandrine BERTETIC***, ***Frédéric SENECA*** et ***Valérie MERCIER-VALERO***) qui font réellement tourner Géoazur.

Il y a tout de même quelques personnes que j'aimerais remercier tout particulièrement pour les petits coups de pouce en plus: pour les sushis (***Julie SCHNEIDER***), les soirées (***Maurin VIDAL***), les discussions scientifiques et autres (***Christophe RENAC***), les cafés et les mots-croisés au soleil du matin (***Chrystele VERATI***). Sans oublier les membres de l'équipe enseignante de Valrose.

Merci aux amis thésards maintenant docteurs avec qui j'ai pu passer d'innombrable bons moments, toujours là pour partager (…les pétages de câble) : ***Benoit DERODE***, ***Flor BARAT***, ***Marianne MAROT*** et ***Clara CASTELLANOS LOPEZ*** merci pour ces moments de réconfort. Je crois qu'ils ont été autant bénéfiques pour vous que pour moi. Merci à ***Swann ZERATHE*** en particulier pour la pêche ainsi qu'à ***Auré SALA*** pour l'avoir laissé venir avec moi.

Je voudrais aussi remercier ceux pour qui la fin arrive ainsi qu'aux nouveaux qui sont arrivés alors que j'avais déjà commencé cette aventure. Merci ***Maëlle KELNER***, ***Cécile JOUBER***, ***Clément VITARD***, ***Chloé LOURY***, ***Flor MARY***, ***Virginie HASSOUN*** pour avoir partagé les pauses café, les prises de tête tout comme les fous rires et moments de décrochage. Je n'oublie pas ***Sadrac SAINT-FLEUR*** et ***Alain DUJARDIN*** et les aventures viennoises. Il y a aussi ***Clément PERRIN***, ***Quentin BLETERY*** et ***Nestor CERPA GILVONIO***, ***Julien BALESTRA***, ***Jérémy GIULIANO*** et ***Yevgeniya SHEREMET*** avec qui j'ai toujours apprécié discuté et rigoler sans oublier l'ami brésilien ***Edouardo FONTANA*** qui m'a appris qu'il y a toujours 2 choses…

Merci à ***J-C***, à ***Alex (Roger)***, à ***Lou***, au ***Lolo du Ghetto***, à ***Lou Scambi (le bienheureux)***, au ***Bastou'***, au ***Dodo (le dernier des dodos)***, à ***Wahib*** et tant d'autres amis de Nice qui ont fait de cette période une réelle aventure pleine de rebondissement et d'inattendus.

Maintenant voilà le tour des potes et la famille. ***Guillaume LEVACHER*** et ***Emma DECOUTRYE***, ***Marie-Carmen*** et ***Michel LEVACHER***, ***Stan LEDOCHOWSKI (Stashu)***, ***Olivier VAN DOOREN (alias Zitoon, alias Wone-2, alias Obi-wone, alias Le Belge, alias Vando)***, ***Antoine SERIS*** ainsi que son frère ***Pierre***, ***Jérôme PRAT*** et ***Gwén RIVIERE***, ***Maître Vince***, ***Adeline VOLLANT***, ***Julien CAILLON*** et sa femme ***Anne-Laure BILLAUD-CAILLON***, ***Magalie DEJOB*** et ***la X-Krew***, je vous dois à tous un grand merci pour le soutien que vous m'avez montré lorsque j'ai pris ma décision de partir de Lyon pour poursuivre ma

passion. Merci aussi pour l'accueil et l'hospitalité que vous m'avez offert à chaque fois que je remontais dans ma ville natale.

Je me sentirai mal si je ne prenais le temps de remercier les coloc' qui m'ont soutenu mais surtout supporté au cours ces deux dernières années, merci ***Bruno SCALABRINO***, ***Antony SARLIN*** et ***François LEVIEZ***.

Merci donc à tous les potes et d'innombrable autres (lyonnais, azuréens, valrosiens, villefranchois, sophipolitains parisiens, géorgiens, montpelliérains, sud-américains, turcs, italiens, espagnoles…) que je ne vois pas aussi souvent que j'aimerais, c'est toujours un plaisir de vous retrouver.

Enfin, je tenais à remercier mes 'co-bureau' que j'ai appris à connaitre aux cours de ces années de thèse ; ***Guillaume SANCHEZ***, ***Romain DARNAULT***, ***Adrien ROMAGNY*** et tout particulièrement l'ami ***Victorien BAUVE*** (*alias* ***Vickey Ryder***, *alias* ***Vickey sans cœur***,…) personnage extrêmement sympathique, serviable et toujours d'une vraie rock attitude rassurante, parfois déconcertante. Je pense que tu seras d'accord avec moi quand je dis que tout au long de ces 6 ans (Master 1, 2 et puis la Thèse), la cohabitation n'a certes pas été un exercice facile mais qu'il est bon d'avoir un ami à qui parler, contre qui faire rebondir des idées, envers et avec qui se lamenter, avec qui rigoler et pleurer, et même avec qui jouer en bourse. J'en garderais un très bon souvenir (les karaokés *« ...à base de popopopop »*, les soirées dans le vieux, les terrains, les innombrables discussions sur hydro-séismicité, le découplage socle/couverture, la géodynamique, l'héritage …la meilleure chartreuse-ito, qui gagnerait à la courte-paille et j'en passe…). Voilà, on a tous les deux réussi à la finir cette thèse. D'autres horizons et projets s'ouvrent à nous maintenant. Bon courage mon ami.

Pour finir, je tiens à exprimer ma profonde gratitude envers ***ma mère***, ***mes grands-parents*** ainsi qu'à ***mon frère, sa femme et leurs deux filles*** qui ont été une source de soutien et d'encouragement jusqu'au bout.

…à la mémoire de mon père.

Etudie, non pour savoir plus, mais pour savoir mieux.

Résumé

Dans de nombreuses chaînes de montagnes, on observe des témoins du processus d'obduction, correspondant au transport de la lithosphère océanique sur la croûte continentale. Le paradoxe intrinsèque de ce phénomène est celui-ci : des roches denses ($\rho>3$) se retrouvent au-dessus de roches moins denses ($\rho\approx2,7$). Les processus à l'origine de cette bizarrerie tectonique sont encore mal compris.

Les ophiolites du Petit Caucase et du NE de l'Anatolie correspondent à un exemple extrême de ce phénomène puisqu'on constate un transport de fragments de lithosphère océanique sur plusieurs centaines de kilomètres, à l'échelle de l'ensemble d'une bordure continentale (>1000 km) vers 90 Ma.

En adoptant une stratégie pluridisciplinaire lors de l'étude de ces ophiolites, nous avons pu préciser l'évolution des premiers stades de la fermeture néotéthysienne et en conséquence l'obduction de ces dernières, tels que :

- L'existence d'un domaine océanique continu d'est en ouest en subduction sous l'Eurasie, séparant l'Eurasie (au nord) de l'ensemble continental Sud-arménien-plateforme Taurides-Anatolides (au sud).
- La genèse d'un domaine océanique dans un contexte de supra-subduction à arrière-arc par ouverture lente, attribué à la formation de ces ophiolites, entre le Jurassique inférieur et Crétacé inférieur (c.180~150 Ma).
- L'obduction quasi simultanée de ces ensembles ophiolitiques, tout au long de la suture d'Izmir-Ankara-Erzincan et Sevan-Akera au Turonien-Coniacien-Santonien (c. 94~85 Ma).
- Un métamorphisme d'unités à la base de ces ophiolites (la semelle ophiolitique) permettant de contraindre leur dynamique de mise en place.
- Un volcanisme dans le bloc continental sud-arménien permettant de proposer une évolution des structures tectoniques inédites vers 160~130 Ma.

Ces données suggèrent fortement une mise en place commune de l'ensemble de ces corps ophiolitiques de la région d'étude sous la forme d'une nappe, dont l'épaisseur actuelle est très réduite (quelques kilomètres tout au plus). Ceci en fait l'une des plus grandes nappes ophiolitiques obduites du globe (à l'affleurement dans une chaîne de collision).

La modélisation numérique a validé l'hypothèse que la mise en place de cette nappe s'est faite grâce à des conditions thermiques particulières. Elle suggère que l'obduction d'ophiolites vieilles nécessite un état thermique de la lithosphère océanique proche de celui d'une lithosphère jeune (0-40 Ma). Un tel état thermique est suggéré pour les ophiolites du Caucase s.l. par la mise en place de laves alcalines sur l'ophiolite avant obduction sous forme de monts sous-marins et/ou de plateau océanique au Crétacé inférieur. Ceux-ci bloquant la subduction sous l'Eurasie expliquent également la quiescence du volcanisme sur cette marge, et le contexte de forçage tectonique de l'autre côté de l'océan, conduisant à l'obduction simultanée sur le bloc continental arménien-anatolien et sur l'Arabie.

Abstract

Within many mountain ranges slivers of preserved oceanic lithosphere evidence tectonic processes responsible for their emplacement on top of the continental crust. The first order anomaly inherent to this phenomenon is that dense rocks ($\rho>3$) end up on top of less dense rocks ($\rho\approx2.7$). The processes responsible for such a tectonic oddity remain uncertain.

The ophiolites of the Lesser Caucasus and NE Anatolia are prime examples of this phenomenon, tectonic transport of fragments of oceanic lithosphere is evidenced on the entire continental marge (>1000 km) around 90 Ma.

The multidisciplinary approach used throughout the study of the ophiolites of the Lesser Caucasus and NE Anatolian regions yielded clues specify the evolution of the Tethys and consequently the obduction of the ophiolites. These results include:

- The existence of a continuous oceanic domain, from East to West, separating Eurasia (to the North) from the South Armenian Block-Taurude-Anatolide Platform (to the South). This ocean was subducting towards the North under the Eurasian margin.
- The creation of oceanic crust in a supra-subduction to back-arc setting, through a slow ocean spreading process between Early Jurassic and Early Cretaceous times (c. 180~150 Ma).
- Nearly simultaneous obduction along the Izmir-Ankara-Erzinncan and Sevan-Akera suture zones of the ophiolites during Turonian-Coniacian-Santonian times (94~85 Ma).
- Directly under the ophiolites, metamorphic units (ophiolitic sole) allow us to constrain the emplacement of the ophiolites.
- Volcanism in the South Armenian Block allows us to propose an unprecedented evolution of the tectonic structures between c. 150~130 Ma.

This dataset strongly suggests common emplacement of the ophiolites of the study area, resembling a thrust sheet. This would be one of the biggest ophiolite nappe complexes in the world (outcropping in a mountain range).

Numerical modeling validates the hypothesis that emplacement of the ophiolitic nappe is due to particular thermal conditions. It suggests that in order to obduct old oceanic lithosphere obduction it needs to have a thermal state close to that of young oceanic lithosphere (0-40 km). Such a thermal rejuvenation is supposed for the ophiolites of the Caucasus s.l. evidenced by alkaline lavas emplaced on the ophiolite prior to the obduction event during the Late Cretaceous. Resulting seamounts and/or oceanic plateaus upon entery of the subduction zone under Eurasia would block it. This is compatible with the observed gap in the volcanism along the Eurasian margin as well as the obduction event on the South Armenian Block-Taurude-Anatolide Platform and Arabia.

Introduction

Dans de nombreuses chaînes de montagnes de collision, des assemblages de roches ultrabasiques (pour la première fois décrites par Brongniart dans les Apennins en 1821 comme des ophiolites) et basiques ont été identifiés, en général associées avec des sédiments pélagiques. Depuis les années 1970 (Penrose field conference, 1972), il est classiquement admis que ces assemblages représentent des lambeaux de lithosphère océanique transportés sur la croûte continentale. Dans Coleman (1971) le paradoxe intrinsèque de ce phénomène fut mis en avant : des roches denses (>3) se retrouvent au-dessus de roches moins denses (~2,7). Pour expliquer ceci Coleman évoque l'obduction comme le processus qui conduit à la formation d'un complexe ophiolitique, fonctionnant au premier ordre avant la collision dans le cycle de Wilson. Mais la question mérite d'être posée : l'obduction est-elle un mécanisme intrinsèque ou correspond-elle à un 'simple' mécanisme de subduction continentale ? Par ailleurs plusieurs questions découlent de la première : Quelles sont les forces à l'origine d'un tel transport ? Dans quels contextes géodynamiques particuliers peut-on envisager des obductions ? Existe-t-il différents types d'obductions ?

A travers le globe, il y a environ 150 ophiolites identifiées dans des chaînes de montagnes. L'âge de ces ensembles ainsi que celui de leur mise en place sur une lithosphère continentale s'étale de 3.8 Ga, au Groenland (Ophiolites d'Isua), à 2~3 Ma, au Chili (Ophiolites de Taitao) (**Figure 1**). La gamme de distribution temporelle de ces objets suppose qu'il s'agit d'un processus ayant couramment accompagné la tectonique des plaques dès son origine avec la formation de plaques suffisamment rigides et différenciées. Cependant, l'ambiguïté du terme « ophiolite » nécessite une clarification. En effet, deux genres ayant des caractéristiques propres sont regroupés sous cette dénomination.

Le premier genre correspond à des ophiolites non-métamorphisées, dites aussi préservées. Un exemple bien connu en Europe est le massif ophiolitique du Chenaillet qui se trouve tout proche de la ville de Briançon dans les Alpes occidentales françaises. Cette ophiolite est principalement constituée de péridotites serpentinisées traversées par des gabbros. L'ensemble est recouvert par des édifices volcaniques ayant produit des basaltes en coussins (Cady, 1995; Chalot-Prat *&* Manatschal, 2202a; 2002b; Manatschal *et al.*, 2002; Chalot-Prat, 2005). Il s'agit d'une section extrêmement bien préservée d'une ancienne lithosphère océanique obduite sur un prisme d'accrétion métamorphique et une lithosphère continentale sous-charriée lors de la collision alpine. Le deuxième genre d'ophiolite est connu

comme ophiolites métamorphisées ou subduites. Le complexe ophiolitique du Mont Viso est de ce genre, situé dans la région du Piémont il constitue l'un des plus hauts sommets des Alpes occidentales italiennes. Les métagabbros présentent des transformations minéralogiques dans un contexte de haute pression. En effet, ils ont été métamorphisés dans les conditions des faciès schiste bleu (marqué par la présence de glaucophane) et éclogitique (éclogites à grenat, phengite et jadéite) (Lombardo *et al.*, 1978; Tricart & Lemoine, 1986; Philippot, 1988; Lagabrielle & Polino, 1988; Schwartz, 2000; Agard *et al.*, 2002; Lardeaux *et al.*, 2006; Tricart & Schwartz., 2006; Yamato *et al.*, 2007; Guillot *et al.*, 2009; Schwartz *et al.*, 2009). Il s'agit ici de roches de haute à ultra-haute pression exhumées, témoins d'une ancienne subduction en partie responsable de la fermeture de l'océan alpin.

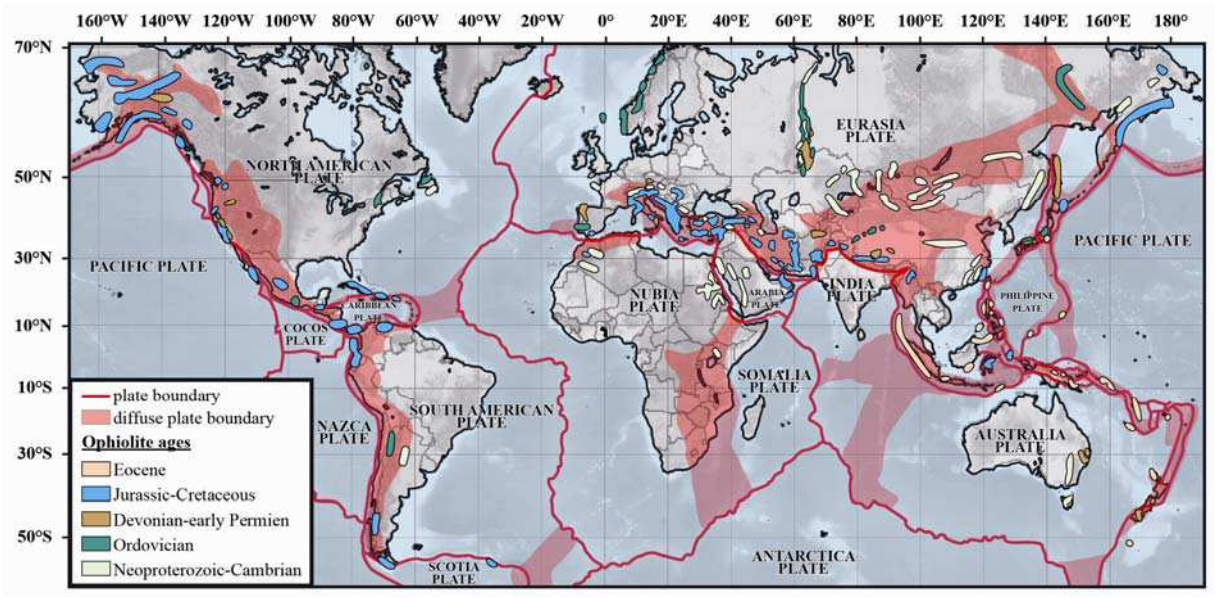

Figure 1 - Distribution des ophiolites Neoprotérozïque et Phanérozïque d'après Vaughan & Scarrow (2003), modifiée.

Ainsi, l'on constate que le terme d'ophiolite ne distingue pas les fragments de lithosphère océanique entraînés en subduction de ceux ayant échappé à celle-ci (et pour lesquels seuls le terme d'obduction peut être considéré pertinent).

Concernant désormais le mécanisme d'obduction. Différents modèles sont proposés.

(1) La première catégorie de modèles suppose qu'il s'agit d'une variante de subduction continentale, un modèle initialement proposé par Davies (1977). Dans ce contexte, une lithosphère continentale fortement couplée au slab dense éclogitisé est tiré dans une subduction intra-océanique sous une lithosphère océanique comme cela est proposé pour le Chenaillet (e.g., Lardeaux, 2013, *et les références qui y figurent*), les ophiolites himalayennes de Tso Morari (Mascle & Guillot, 2012), ou l'ophiolite d'Oman (Agard *et al.*, 2007, Yamato *et al.*, 2007; Chemenda, 1994, *et les références qui y figurent*), entre autres.

(2) D'autres auteurs considèrent que l'obduction est initiée au sein du domaine océanique en réponse à un phénomène global anormal : augmentation de la vitesse de plaques, (Agard *et al.*, 2007); point chaud (Vaughan & Scarrow, 2003)…

Par ailleurs, concernant le lieu de l'initiation de l'obduction, différents modèles sont envisagés, proposant (i) l'initiation de l'obduction soit au niveau d'une dorsale médio-océanique (Coleman, 1971; Moores & Vine, 1971; Cann, 2003, *et les références qui y figurent*) soit (ii) dans un bassin marginal (Saunders & Tardey, 1984; Rautenschlien *et al.*, 1985; Hébert & Laurent, 1990; Thy & Xenophontos, 1991; Beccaluva *et al.*, 1994; Bédard *et al.*, 1998; Dilek *et al.*, 1999; Shervais, 2000; Dilek & Flower, 2003), ou bien encore dans la lithosphère océanique indifférenciée, dû au flambage de celle-ci (Agard *et al.*, 2007)

Dans le cas où la lithosphère océanique s'est formée au-dessus d'une zone de subduction (ophiolites de type supra-subduction, SSZ, Pearce *et al.*, 1984; 2003), l'obduction est possible lorsque l'arrivée d'une marge continentale entre dans la subduction et bloque son fonctionnement. La zone de subduction sert alors de zone de charriage. Dans cette hypothèse, une semelle métamorphique se forme dans cette zone par transformation des sédiments et laves de la plaque plongeante (Searle & Cox, 1999).

Si les ophiolites se forment au niveau d'une dorsale médio-océanique, dans un premier temps un écaillage intra-océanique se fait au niveau de la dorsale. Lors de cet écaillage, les laves et sédiments chevauchés par la lithosphère océanique chaude sont rabotés et métamorphisés. Ils constituent alors la '***semelle métamorphique***' de l'ophiolite.

Lors de la fin de l'obduction proprement dite, l'ensemble « ophiolite et semelle métamorphique » peuvent continuer leur progression sur la marge continentale par glissement gravitaire dans un bassin d'avant pays formé sur la marge continentale par flexure et/ou subsidence (Goguel, 1948; Merle, 1998; Rawling & Lister, 2002; Lagabrielle *et al.*, 2005; Chardon & Chevillotte, 2006; Lagabrielle & Chauvet, 2008; Ulrich, 2010; Lagabrielle *et al.*, 2013), ou bien par un sous-charriage prolongé de la lithosphère continentale (ex : Himalaya).

Le travail de recherche présenté dans ce mémoire concerne les ophiolites du nord-est de l'Anatolie en Turquie et du Petit Caucase en Arménie (**Figure 2**). Le choix porté sur ces ophiolites, qui ont été depuis une dizaine d'années étudiés en détails répond à deux constatations essentielles concernant l'âge et la dimension des objets obduits.

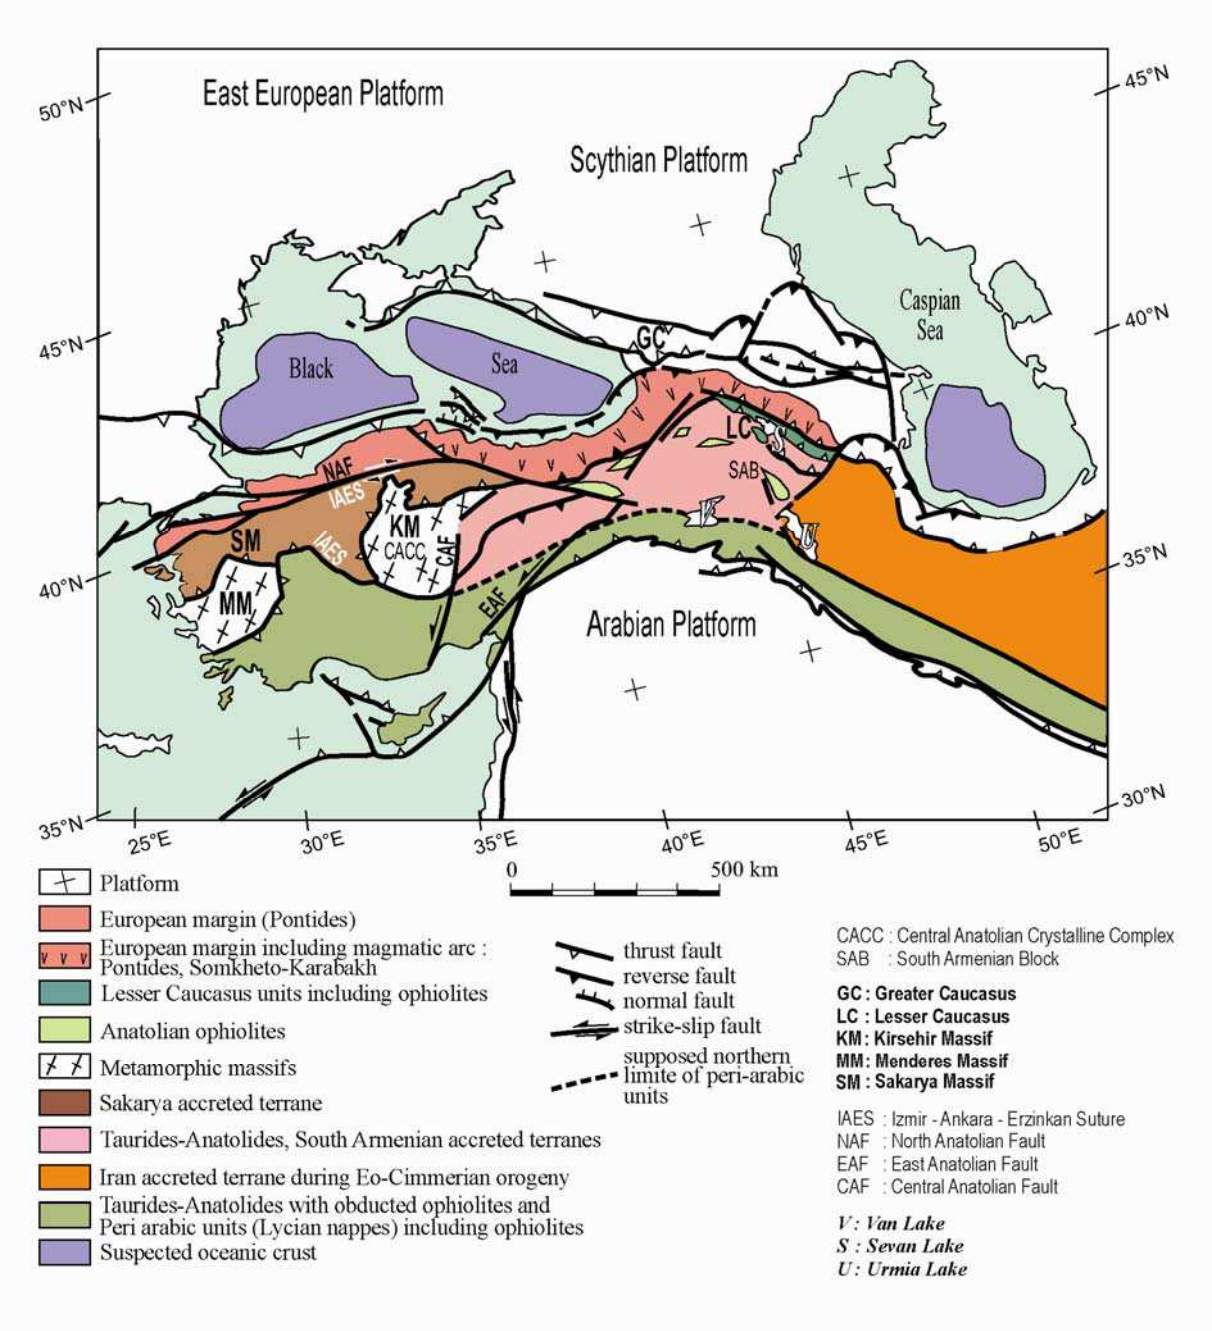

Figure 2 - Carte structurale schématique des régions du Moyen-Orient et du Caucase d'après Avagyan et al. (2005), modifiée.

(i) La lithosphère océanique est âgée d'environ 80 à 50 Ma au moment de son obduction (qui dure 10 millions d'années au maximum), elle est donc dans ce cas déjà très refroidie et dense et ne semble pas compatible avec un modèle ou l'obduction pourrait être initiée au niveau d'une ride océanique. Ainsi, l'écart d'âge entre la formation et la mise en place des objets rendent possible l'identification de différents processus géodynamiques pouvant être responsables de cette obduction (variation des vitesses d'accrétion océanique, de subduction, mise en place d'autres zones de subduction, apparition de point chaud…). La collision

intervenant plus tard (10 millions d'années après dans l'exemple du Petit Caucase) n'a par conséquent pas d'influence sur la structure et le mode de l'obduction.

(ii) Les ophiolites font apparemment partie d'un même ensemble qui a été transporté sur des distances importantes (> 100 km de large sur plusieurs centaines de kilomètre de long). Ce paramètre est essentiel pour définir le mécanisme responsable de l'obduction. En effet, on peut par exemple penser que ces dimensions sont trop importantes pour pouvoir être uniquement causées par une obduction initiée par un processus de subduction continentale.

Beaucoup de travaux se rapportant à l'Arménie ont été rédigés en arménien ou en russe. Ils constituent avec les récents travaux effectuées par les équipes françaises sur ce domaine, une base d'études ayant comme objectif d'étudier l'origine de ophiolites (genèse, géométrie, dynamique,…). Les travaux à propos des ophiolites turques et iraniennes, axés sur leur origine et mise en place, se sont portés depuis peu plus particulièrement sur leurs continuités latérales. Dû à des différends politiques la coordination scientifique entre ces pays est difficile. Pour ces raisons il est nécessaire de reprendre ces données, de les comparer, de les synthétiser. Nous avons ainsi extrait les données et résultats antérieurs afin d'exposer un inventaire des ophiolites nord téthysiennes de la zone d'étude. Ainsi, nous avons pu révéler les points obscurs sur leur genèse, sur leur structure, sur les processus responsables de leur mise en place. Ces données viennent en complément de nouvelles investigations menées en collaboration avec des équipes locales (arménienne et turque).

Notre étude concerne plus précisément l'analyse des processus magmatiques, métamorphiques et tectoniques mis en jeu lors de la mise en place d'une nappe de lithosphère océanique préservée (non-métamorphique) sur un domaine continental. La fermeture de l'espace océanique nord téthysien a conduit à des subductions et à l'obduction de segments de lithosphère océanique (métamorphisée ou préservée). Plus précisément, nous avons étudié les ophiolites situées au sud de la suture nord téthysienne (Izmir-Ankara-Erzincan-Amasia-Sevan-Akera) entre Refahiye (Turquie) et Vedi (Arménie) (**Figure 3**). Ces ophiolites chevauchent un domaine constitué de plusieurs microcontinents (Tauride, Anatolide et Sud Arménien). La fermeture océanique est suivie d'une collision continentale (à partir du Crétacé terminal-Paléocène). Cette dernière phase a découpé et décalé les corps ophiolitiques et recouvert ceux-ci par une épaisse couverture volcano-sédimentaire.

Hercynian basement
Proterozoic metamorphic basement

Figure 3 - Carte structurale du NE de l'Anatolie et du Petit Caucase d'après Hässig et al. (2014).

Du fait de la grande homogénéité des âges des ophiolites et des structures le long de l'Anatolie (e.g., Çelik *et al.*, 2011), l'exemple étudié est l'un des plus remarquables à l'échelle globale. Nous expliquerons qu'il est envisageable que l'enchaînement des processus proposés dans cette zone étude puissent également s'appliquer aux ophiolites et leurs mise en place plus à l'est ainsi qu'à l'ouest, à l'échelle de toute l'Anatolie. La fraîcheur et les bonnes conditions d'affleurement étant propices à en faire un cas d'école concernant le processus d'obduction.

Afin d'exposer tous les arguments et illustrer le modèle d'obduction dans la zone d'étude, ce mémoire s'articule en six parties (chapitres, intégrant cinq publications en tant que 1er auteur dont deux publiées et trois soumises à révision) :

1- Le premier chapitre reprendra les travaux antérieurs depuis les années soixante ainsi que les débats en cours concernant les questions de composition, d'âge de formation et de mise en place des ophiolites.

2- Le deuxième chapitre développera en deux sous-chapitres l'étude géologique, pétro-géochimique et métamorphique, ainsi que ses implications, de la région frontière entre les domaines ophiolitiques arméniens et turcs (Amasia, Arménie):

   - Le premier sous chapitre analyse et traîte les caractéristiques structurales et pétro-géochimiques des ophiolites d'Amasia (Arménie). Cette zone ophiolitique comprend une série complète de différenciation avec des gabbros et des basaltes montrant des affinités de type MORB et une deuxième série de laves alcalines avec des affinités de type OIB. Les nouvelles données de datations obtenues sur les hornblendes des gabbros suggèrent la formation d'une croûte océanique au Jurassique moyen. Cette partie fait l'objet d'un article publié dans *Tectonophysics*.
   - Le second analyse et traite les caractéristiques structurales et pétro-géochimiques des roches métamorphiques de la semelle des ophiolites d'Amasia. Cette zone ophiolitique comprend une écaille d'amphibolite à grenat étiré dans un mélange tectonique de faciès schiste vert en position basale du corps ophiolitique. Les nouvelles données de datations obtenues sur amphibole et mica blanc de l'écaille d'amphibolite à grenat permettent de mettre en évidence un chemin PT-t antihoraire. Cette partie fait l'objet d'un article soumis à *Journal of the Geological Society*.

3- Le troisième chapitre analyse l'ensemble des données (structurales, pétro-géochimiques et géochronologiques) de toute la zone d'étude concernant la mise en place de ces différentes ophiolites concluant sur leur appartenance à une seule nappe ophiolitique. Cette partie apporte pour la première fois une synthèse des données récentes sur les roches magmatiques, métamorphiques ainsi que sur les contraintes stratigraphiques entre les territoires arménien et turc. Elle fait l'objet d'un article publié dans *Geodinamica Acta*.

4- Le quatrième chapitre explore l'histoire métamorphique du socle cristallin du microcontinent sud arménien dans la seule localité où il affleure, la région de Tsaghkuniats près de Bjni (juste au Nord de Erevan). Cette partie apporte pour la première fois des données géochronologiques sur les événements thermiques affectant la lithosphère continentale arménienne avant l'obduction par les ophiolites étudiées, mais propose aussi un scénario géodynamique inédit intégrant une subduction vers le sud, sous les blocs continentaux chevauchés par la nappe ophiolitique. Elle fait l'objet d'un article soumis à *Journal of Asian Earth Sciences*.

5- Le cinquième chapitre analyse les processus géodynamiques anté-obduction impliqués dans la zone d'étude. Il en ressort un modèle conceptuel élaboré à partir des données géologiques de surface. Ce chapitre se caractérise principalement par une discussion concernant la configuration de base du modèle d'obduction proposé par la suite, en conclusion de cette thèse. Elle fait l'objet d'un article soumis à *Geological Society of London, Special Publication*.

6- Le sixième chapitre sert de conclusion. Les nouvelles données et nouveaux résultats présentés dans les chapitres précédents sont résumés afin de répondre aux questions scientifiques que nous nous étions fixées au début de cette étude. Dans cette partie nous présentons une modélisation intégrant les caractéristiques générales du domaine océanique maintenant disparu dont les ophiolites sont les seules reliques, sur la base de la reconstitution des événements géodynamiques successifs proposée pour les ophiolites du Petit Caucase-NE Anatolie. En conséquence, une discussion des processus à l'origine de l'obduction est proposée pour expliquer le cas d'étude et plus généralement le mécanisme d'obduction.

<u>Chapitre 1</u> – Ophiolite/Obduction : historique et problèmatique de la thèse

« Ce qu'on dit être nouveau en ce monde, c'est l'histoire qu'on ignore. »

Harry S. Truman

Ce travail de recherche concerne le processus de mise en place des ophiolites du Petit Caucase (Arménie) ainsi que celles de NE Anatolie (NE Turquie). Avant de présenter les nouvelles données, analyses et interprétations, nous décrirons les données antérieures, qui sont aussi nombreuses que de nature différente. Afin de mieux argumenter les reconstructions proposées par la suite nous passerons tout d'abord en revue les ensembles majeurs d'ophiolites recensés dans le monde pour en dégager les modèles de formation et de mise en place (obduction) principaux. Cela permettra également de mieux développer les particularités des ophiolites de la zone d'étude par la suite.

La zone d'étude s'étend sur plus de 700 km d'est en ouest et plus de 150 km du nord au sud. Les articles portant sur la partie arménienne sont pour la plupart publiés avant les années 1990, écrits en russe ou en arménien (et synthétisés dans la thèse de Galoyan, 2008). Certaines sources bibliographiques portant sur la région de NE Anatolie, résumés de conférences et communiqués, n'ont été publiées qu'en turc. Cela justifie le besoin d'une synthèse de ces différents travaux, afin de bien introduire cette thèse. Une synthèse des résultats antérieurs est présentée pour en extraire les points obscurs, tant sur le plan des structures que sur le plan de l'évolution géodynamique, depuis la genèse des ophiolites jusqu'à leur obduction.

I.1 Concepts

1.1 Ophiolite

Le mot « ophiolite », du grecque '*ophi*' (serpent), fut utilisé pour la première fois par le géologue français Alexandre Brongniart en 1813 (Brongniart, 1813) pour caractériser la texture et la minéralogie de roches majoritairement composées de serpentine. En 1821, une corrélation a été décrite entre ces serpentinites et d'autres roches telles que des gabbros, roches volcaniques et des chailles (roches siliceuses) (Brongniart, 1821). Remarquons toutefois que dans Brongniart (1827) le terme « ophiolite » est utilisé exclusivement pour désigner une minéralogie serpentineuse. Fouqué & Lévy (1879) introduisirent le terme dérivé « ophite » pour désigner les gabbros et basaltes associés.

Dans Suess (1909), l'auteur décrit la disposition de niveaux riches en serpentinites en nappes incorporées dans les chaînes de montagnes. C'est en 1926 que ce type d'association de roches ou « Alpine Type Peridotites », affleurant dans des chaînes de montagnes ont été désignées comme des ophiolites (Benson, 1926).

Le sens moderne du terme « ophiolite » est en grand partie à attribuer à Gustav Steinmann. Steinmann (1905, 1927) décrivit les relations existant sur le terrain entre des serpentinites, des gabbros, des basaltes et des radiolarites. Steinmann (1927) propose alors d'utiliser le terme ophiolite pour désigner cette association de roches. L'origine de l'ophiolite à de grands fonds océaniques est alors établie tout comme la relation pétrogénétique entre roches ultramafiques et mafiques. L'association de serpentinites, roches magmatiques, et radiolarites a conduit à l'expression « la trinité de Steinmann ».

Dès la fin des années 1950s, le développement des concepts aboutissant à la tectoniques des plaques a donné lieu à des études concernant l'origine des ophiolites (i.e. Oliver *et al.*, 1969; Coleman, 1971; Dewey *&* Bird, 1971; Moores *&* Vigne, 1971). Les travaux menés par Hess (1955, 1962, 1965), Wilson (1959), Gass (1963), Ricou (1968), Vuagnat (1968), Moores (1969) et Thayer (1969) ont grandement participé à l'évolution du terme « ophiolite ». Les données géophysiques suggèrent que la stratification de la croûte océanique est semblable la succession de roche dans les complexes ophiolitiques (Salisbury *&* Christensen, 1978).

Deux grandes écoles de pensée sont alors apparues : (1) la première suivait les travaux de Steinmann (1927), Brunn (1959), et Aubouin (1965) tandis que (2) l'autre suivait Hess (1955) et Dietz (1963). Concernant les premiers (e.g. Aubouin, 1965) les ophiolites sont générées par la différenciation d'extrusions profondes gigantesques sur le fond marin. Les seconds (e.g., Hess, 1955) proposent que ophiolites représentent le fond de l'océan ; et sont mises en place lors d'une phase orogénique. Ce modèle sera également élaboré plus tard par Miyashiro (1973) sur la base d'analyses géochimiques. Les modèles de Hess et Dietz ont formé la base du modèle de la tectonique des plaques proposé par Le Pichon *et al.* (1976).

Wilson (1959) a été parmi les premiers à cartographier avec précision et à fournir d'excellentes illustrations des caractéristiques macroscopiques et microscopiques des ophiolites de Chypre. Les études suivantes (i.e. Gass, 1963; Moores *&* Vine, 1971; Miyashiro, 1973; Panayiotou, 1980; Robinson *et al.*, 1987; Malpas *et al.*, 1990) ont fait du complexe ophiolitique de Troodos l'une des ophiolites les plus connues du monde. Parmi les nombreuses découvertes effectuées à Chypre, figurait celle du complexe filonien, qui a eu un impact profond sur les modèles de chambre magmatique et a conduit à l'hypothèse que les ophiolites se forment au niveau d'une dorsale océanique.

En septembre 1972, lors de la conférence de Penrose, une première définition internationalement reconnue par les spécialistes de l'époque a été proposée pour les ophiolites (Penrose field conference, 1972). Les ophiolites ont été assimilées à des fragments de

lithosphère océanique créée au niveau d'une dorsale médio-océanique. Un volume conséquent de données sismiques du fond de l'océan rendait tentant de faire la comparaison entre la série ophiolitique préservée observée sur le terrain, plus tard appelé « Penrose ophiolite », et la stratigraphie de la lithosphère océanique obtenue par les méthodes géophysiques.

Au cours des années, suivant l'élaboration de cette définition, de nombreuses études intégrant des outils de discrimination géochimique ont conduit à la reconnaissance d'une grande diversité d'ophiolites. Il devenait évident que des ophiolites pouvaient être générées dans une grande variété d'environnements géodynamiques, non seulement au niveau d'une dorsale médio-océanique, mais aussi dans un contexte d'arc insulaire (Miyashiro, 1973). Le lien entre les ophiolites et les zones de subduction fut discuté par Sun *&* Nesbitt (1978) afin d'expliquer l'origine des basaltes appauvris en Ti (boninites; Cameron *et al.*, 1979). Cela a conduit à l'idée que certaines ophiolites pourraient avoir été formées dans des zones au-dessus des zones de subduction. Ceci déboucha sur le modèle de formation de croûte océanique en zone de supra-subduction (Allègre *et al.*, 1982). Ce modèle est soutenu par Pearce *et al.* (1984) qui met en avant l'hypothèse de Miyashiro (1973). Ainsi Dilek *&* Furnes (2011) ont défini deux catégories d'ophiolites : (1) les ophiolites formées en relation avec le fonctionnement d'une zone de subduction, et (2) les ophiolites formées sans lien direct avec une zone de subduction. L'identification de contextes d'avant- et d'arrière-arc comme analogues actuels d'environnements de formation d'ophiolites (Moores *et al.*, 1984) a marqué un tournant dans la compréhension de l'origine des ophiolites et leur utilité pour reconstruire les contextes tectoniques passés.

Les détails structuraux des ophiolites fournissent des perspectives sur la dynamique de la lithosphère océanique. Nicolas (1989) résume globalement les immenses progrès réalisés dans la compréhension de la pétrogenèse, de l'évolution structurale, de l'obduction et du remaniement des ophiolites et de la lithosphère océanique. Il introduit les notions d'ophiolite de type harzburgite (HOT) et de type lherzolite (LOT) (**Figure 4**). La comparaison des données de forages et des ophiolites à l'affleurement premettra par la suite de relier les ophiolites de type HOT à une dynamique océanique rapide (exemple : la dorsale pacifique), marquée par de forts taux de fusion, et les LOT à une dynamique d'océan lent à ultra-lent (type Atlantique ou Océan Indien), (Lagabrielle *&* Cannat, 1990; Lagabrielle *&* Lemoine, 1997; **Figure 5**).

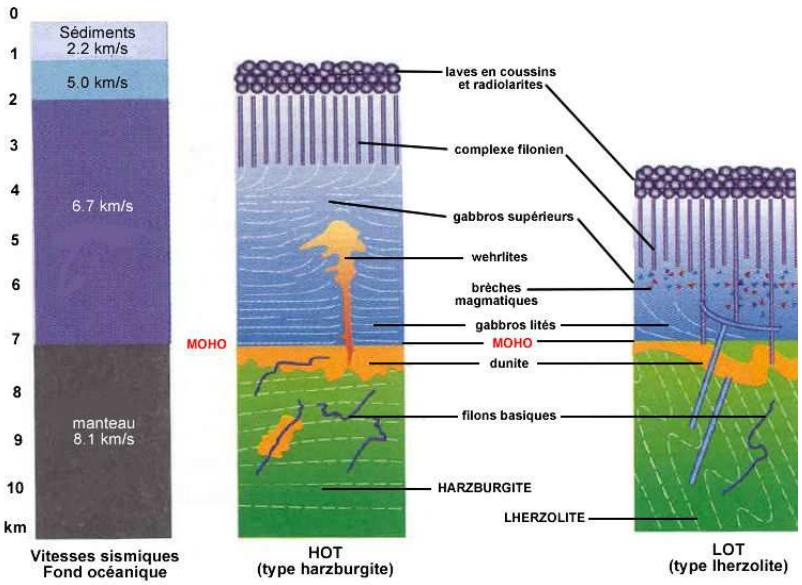

Figure 4 - Profils lithosphériques comparés HOT et LOT, et section définie par la sismique pour un fond océanique 'normal' composé d'une épaisse couche de produits d'origine magmatique (gabbros et basaltes), d'après Vissers & Nicolas (1995) et Nicolas (1997).

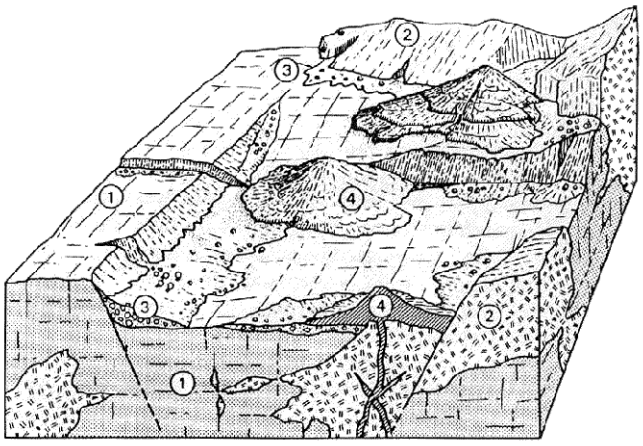

Figure 5 - Schéma d'une ophiolite de ride lente (LOT), d'après l'observation des ophiolites alpines (Lagabrielle, 1987; Lagabrielle *et al.*, 1989; Lagabrielle & Lemoine, 1997). 1, lherzolite serpentinisée (manteau) ; 2, gabbros ; 3, brèches (talus de debris) ; 4, volcans à laves en coussins.

A ces deux types principaux d'ophiolites, il convient également d'ajouter les marges étirées, puisqu'elles comprennent une section de péridotites mises à l'affleurement souvent sur plusieurs centaines de km, appelés 'fonds du 3^{e} type' par Juteau & Maury (1997). Cette mise à l'affleurement survient dans un stade de rifting avancé juste avant l'ouverture océanique proprement dite. Il peut donc exister une continuité entre un fond serpentineux exhumé au cours de mécanismes extensifs (e.g., Lagabrielle, 2009) et une ride lente, puis plus rapide. Ce domaine de transition entre une marge continentale et un domaine océanique 'normal' est communément appelé OCT (Ocean-Continent Transition, e.g., Florineth &

Froitzheim, 1994; Hermann *et al.*, 1997; Manatschal & Nievergelt, 1997; Molli, 1996; Marroni *et al.*, 1998).

Remarquons que ces différents fonds océaniques peuvent conduire à la mise en place d' « ophiolites » sur les marges continentales par des processus d'obduction qui peuvent être fort différents et propres à chaque contexte. La présence d'une grande zone serpentineuse par exemple dans le domaine de l'OCT peut être un des facteurs favorisant l'obduction, tandis que des fonds océaniques plus rapides et ne présentant pas d'OCT pourraient présenter des domaines de faiblesse rhéologique au niveau de la ride (e.g., Coleman, 1981).

Ainsi il devient évident qu'afin de mieux comprendre l'obduction des ophiolites du Petite Caucase et NE Anatolie, nous devons essayer de bien caractériser leur contexte de formation.

1.2 Obduction

Coleman (1971) introduit le terme « obduction » pour décrire le processus de mise en place des ophiolites, ainsi marquant la distinction avec l'habituel sort de la lithosphère océanique, la subduction. Malgré plus de 40 années études, les étapes successives du processus d'obduction sont encore sources de débat (Cluzel *et al.*, 2001; Crawford *et al.*, 2003; Schellart *et al.*, 2006; Wattham *et al.*, 2008; Ulrich *et al.*, 2010; Titus *et al.*, 2011; Cluzel *et al.*, 2012). Différents modèles ont été proposés depuis l'identification des ophiolites comme reliques de domaines océaniques maintenant disparus. L'obduction serait liée aux processus se produisant au niveau des frontières de plaques convergentes (Dewey, 1976). Les relations tectoniques et stratigraphiques résultant de ce processus peuvent présenter une grande variabilité. Par conséquent, il est évident que cette variation du style de mise en place tectonique des ophiolites est à attribuer en partie à la variabilité du contexte tectonique de formation du planché océanique.

Le processus d'obduction peut néanmoins être classé selon quatre catégories (**Figure 6**);

(1) subduction continentale/accretion-collision (Dewey & Bird, 1970; 1971; Church & Stevens, 1971; Dewey, 1976; Smith & Woodcock, 1976; Gealey, 1977; Malpas & Stevens, 1977; Welland & Mitchell, 1977; Searle & Malpas, 1980),

(2) glissement gravitaire/obduction passive (i.e. Williams & Smyth, 1973; Glennie *et al.*, 1973; Stoneley, 1975; Coleman, 1977; Lagabrielle *et al.*, 2013),

(3) propagation gravitaire (i.e. Elliott, 1976; Searle & Malpas, 1980),

(4) jeu de failles transformantes (i.e. Brookfield, 1977; Karson & Dewey, 1978).

Remarquons que ces concepts peuvent être complémentaires ou non selon le contexte de formation du planché océanique considéré. La propagation d'une obduction n'est pas significativement différent de la mise en place de nappes de charriages (Elliott, 1976; Rod, 1982), le matériel déplacé est différent mais les processus physiques sont similaires.

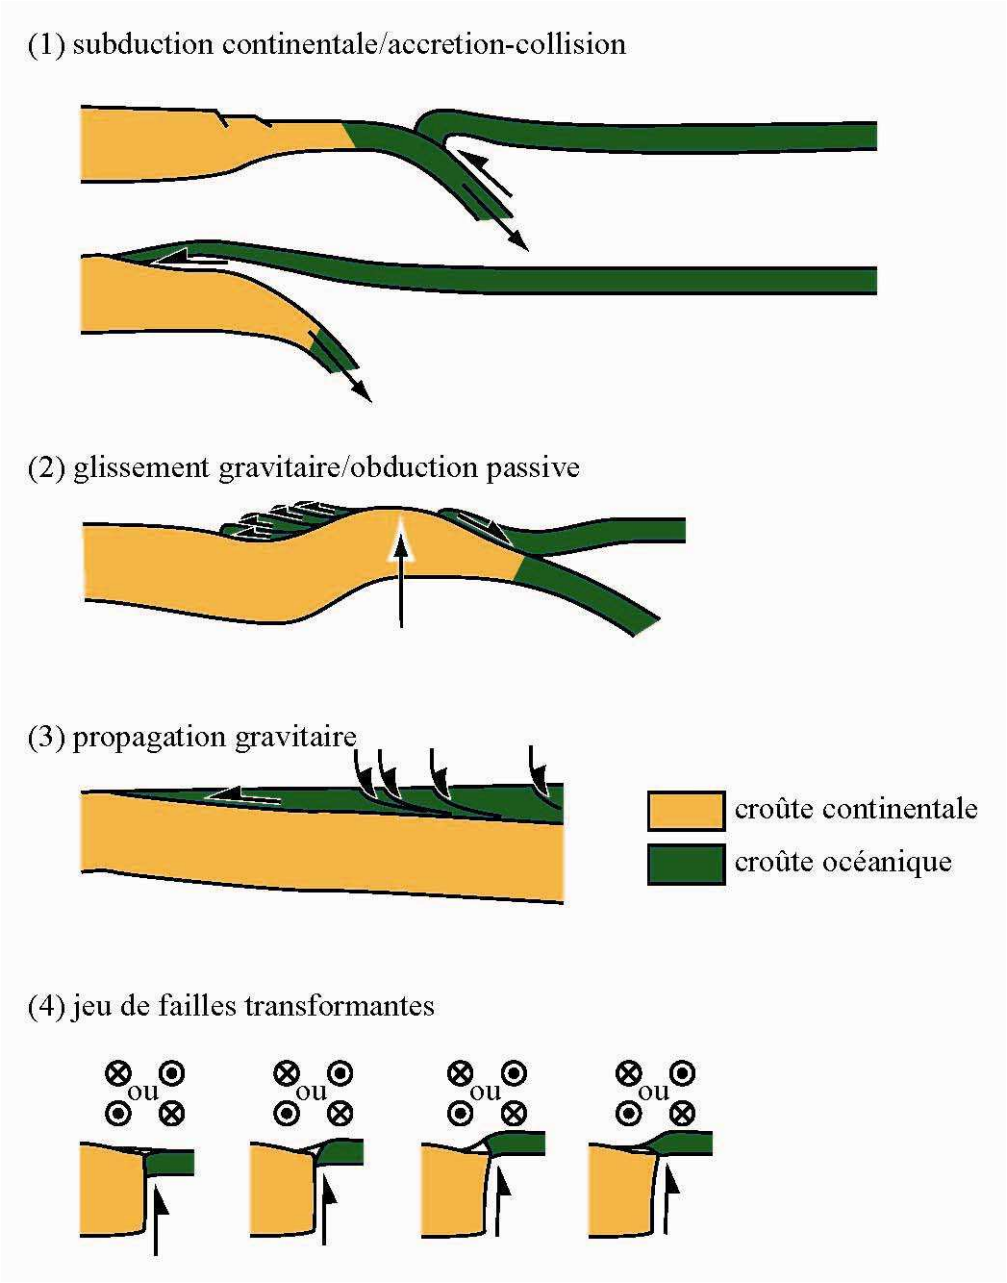

Figure 6 - Schémas illustrant les quatre catégories d'obduction.

Le modèle d'obduction actuellement admis (Coleman, 1981) propose que le transport tectonique des ophiolites sur une marge continentale résulte de l'évolution d'une zone de subduction intra-océanique ou s'initiant à proximité d'une marge. Le domaine océanique entre la marge continentale et la zone de subduction disparait progressivement jusqu'à l'arrivé

de la marge continentale dans la zone de subduction. La subduction évolue de manière à entrainer le continent en profondeur (subduction continentale). McKenzie (1969) argumente que la flottabilité relativement élevé de la croûte continentale est susceptible d'empêcher la subduction continentale. Au cours de cette étape une tranche géante, « une nappe », de lithosphère océanique est poussée sur la marge continentale. Lors des premiers stades de subduction continentale des flyschs, des mélanges tectoniques et des olistostromes contenant des éléments ophiolitiques sont amenées progressivement dans la fosse, alimentant la formation de niveaux transgressifs sur la marge continentale (Dewey, 1976). Les sédiments alimentant ainsi la fosse sont entrainés dans le contact inter-plaque et ainsi métamorphisé (Coleman, 1981). C'est le couplage des contraintes structurales et métamorphiques issues de l'étude des ophiolites elles-mêmes ainsi que celle de toutes les roches métamorphiques sous l'ophiolite (la semelle ophiolitique) qui fournissent les éléments nécessaires pour la reconstruction de scénarios de mise en place. Les chemins PT-t à la fois horaire et antihoraires enregistrés par ces roches métamorphique sont ainsi interprétés comme témoignant d'un sous-charriage (subduction) du domaine continental et le charriage (obduction) du domaine océanique (Searle & Cox, 1999), respectivement. Les reconstructions de l'obduction pour les régions Alpes orientales (Manatschal & Muntener, 2009), Macédonie (Bozovic *et al.*, 2013), Oman (Yamato *et al.*, 2007), Nouvelle Calédonie (Lagabrielle *et al.*, 2013), Californie (Harper *et al.*, 1996), Terre-Neuve (Cawood & Suhr, 1992) et Urals (Brown *et al.*, 2006) limite à 5 Ma l'écart entre la genèse des ophiolites et la subduction continentale, et 20 Ma pour le cycle total entre genèse et emplacement final du corps ophiolitique sur la marge continentale.

Cependant, les causes de ce contexte particulier restent à être précisées. La détermination des conditions permettant à la mise en place de ces objets denses constitués de manteau et la croûte océanique sur un domaine moins dense de croûte continentale peuvent fournir des indices concernant la cause (ou les causes) de telles « bizarreries » géologiques (Agard *et al.*, 2007).

Deux causes de l'obduction sont actuellement discutées. La première est exposée et argumentée par Vaughan & Scarrow (2003) et découle de l'observation que les événements de l'obduction semblent postérieurs au début de la mise en place d'un volcanisme attribué à des panaches mantelliques (Ishiwatari, 1994; Stein & Hoffmann, 1994; Yakubchuk *et al.*, 1994). Ces panaches seraient à l'origine du soulèvement et de l'accélération du mouvement des plaques tectoniques. La modification de divers facteurs, modifiant le couplage au niveau

des zones de subduction, tels que le taux de convergence, la rugosité (ou présence d'aspérités), la flottabilité du panneau plongeant et la dynamique du manteau (Vaughan, 1995). Seules les aspérités majeures, tels que plateaux basaltiques sous-marins, entrant en subduction sont susceptibles d'augmenter de manière significative le couplage interplaque. Aujourd'hui on peut voir cet effet de verrouillage d'une zone de subduction au nord de la Papouasie-Nouvelle-Guinée où le plateau basaltique d'Ontong-Java entre en subduction (Hill *&* Raza, 1999). Les panaches mantelliques seraient également responsables du rajeunissement thermique de la lithosphère océanique.

Ainsi Vaughan *&* Scarrow (2003) propose que l'ensemble des perturbations causé par les panaches mantelliques (baisse de la densité et rajeunissement thermique de la lithosphère océanique, augmentation des vitesses des mouvements horizontaux dans la tectonique des plaques, mise en place de reliefs pouvant perturber le fonctionnement 'habituel' des zones de subduction,…) sont à l'origine de l'obduction de vastes domaines océaniques.

Agard *et al.* (2007) considère que l'obduction sert d'accommodation inertielle à la convergence continentale. Suite à des observations et reconstructions géodynamiques concernant la genèse et la mise en place des ophiolites d'Oman, les auteurs analyses les variations des vitesses de convergence entre l'Arabie et l'Eurasie (Scholz *&* Campos, 1995; Conrad *et al.*, 2004; Heuret *&* Lallemand, 2005) et celle de la subduction du domaine océanique sous l'Eurasie (Platt, 2000). Ces modèles ainsi que les déductions qui en découlent ont permis de corréler l'initiation et propagation de l'obduction d'Oman à une augmentation de la convergence entre l'Arabie et l'Eurasie et de proposer que la subduction sous l'Eurasie était incapable d'accommoder cette accélération de convergence. Ainsi, l'accélération du mouvement de plaques, le ralentissement de la subduction et/ou l'augmentation de la production à la ride sont des facteurs (causes) avancés pour l'initiation de l'obduction.

La cause de l'obduction proposée par Agard *et al.* (2007) n'est pas incompatible avec celle de Vaughan *&* Scarrow (2003). Les auteurs sont en accord avec un modèle dans lequel l'obduction se fait en réponse à la perturbation d'une subduction préexistante bordant le domaine océanique. Ainsi l'obduction serait un processus tectonique compensant une subduction incapable d'accommoder la convergence continentale.

I.2 Contexte général de la zone d'étude

Suite à de récentes études concernant ces ophiolites du Petit Caucase (Galoyan, 2008; Rolland *et al.*, 2009a; 2009b; Danelian *et al.*, 2010; Sosson *et al.*, 2010; Rolland *et al.*, 2010; 2011; 2012) les auteurs sont en accord pour dire qu'elles ont une origine commune. C'est-à-dire que ces lambeaux de croûte océanique préservés (non-métamorphisés) ont appartenu à un même domaine océanique. Celui-ci s'est formé dans un contexte de supra-subduction à arrière arc. Ces interprétations valident l'appartenance de l'ensemble de ces corps à une seule structure, dont la limite nord marque une seule suture (Knipper & Khain, 1980; Adamia *et al.*, 1981; Aghamalyan, 1996; Knipper *et al.*, 1997). L'hypothèse alternative était qu'elle marquait trois structures indépendantes s'appuyant sur leurs orientation, leurs localisation et sur le fait qu'elles n'avaient jamais été chariées (Aslanyan & Satian, 1977; Satian, 2005; Satian *et al.*, 2005).

Les reconstitutions tectonique et géodynamique du Petit Caucase ne sont pas encore précisément déterminées car elles dépendent en grande partie de l'évolution de ces corps ophiolitiques. Ces reconstitutions doivent prendre en compte l'héritage géologique du domaine océanique obducté, acquit depuis le début de son accrétion au milieu du Mésozoïque (Jurassique moyen) jusqu'à son obduction à la fin du Mésozoïque (Crétacé supérieur), qui n'est que peu souvent préservé de la déformation lié au développement de la zone de suture en contexte de collision.

Tout comme dans le Petit Caucase, dans le nord-est de l'Anatolie des affleurements d'ophiolites ainsi que de mélange ophiolitique marquent la zone de suture Izmir-Ankara-Erzincan (Şengör & Yılmaz, 1981; Robertson & Dixon, 1984; Yılmaz *et al.*, 1997; Okay & Şahintürk 1997; Rice *et al.*, 2006, 2009; Özen *et al.*, 2008; Çolakoğlu, 2009; Sarıfakıoğlu *et al.*, 2009). Elles témoignent de la position de cette suture téthysienne par leur allongement presque E-W. Plus au sud, il existe aussi des affleurements en position distale comparable à la zone de Vedi dans le Petit Caucase. Cependant, concernant le calendrier tectonique aucun scénario ne fait l'unanimité contrairement aux ophiolites du Petit Caucase. Par exemple, l'âge de la subduction de la partie nord de ce domaine océanique sous la marge eurasienne est supposé être Jurassique (Adamia *et al.*, 1981; Hess *et al.*, 1995; Nikishin *et al.*, 2003), Cenomanien-Turonien (Yılmaz *et al.*, 1997; Okay & Şahintürk, 1997) ou Albien (Okay *et al.*, 2006). Ceci est également valable pour la fin de cette subduction et par conséquent l'âge de collision continentale qui a successivement été avancé fin Eocène (Peccerillio et Taylor, 1976; Şengör & Yılmaz, 1981; Robinson *et al.*, 1995), Eocène moyen (Yılmaz *et al.*, 1997) ou

Paleocène (Okay & Şahintürk, 1997). Des modèles tectonique alternatif ont été proposés afin d'allier anciennes et nouvelles observations (Okay & Şahintürk, 1997; Rice *et al.*, 2006; 2009; Rolland *et al.*, 2009a; Robertson & Ustaömer, 2012).

I.3 Problèmatique avant thèse

L'objet de cette thèse est de contraindre le processus d'obduction pour les ophiolites provenant de la branche nord de la Néotéthys. Les données étant éparses dans cette région du monde (NE Turquie et Arménie) il convient de trouver les liens entre ces zones. Par conséquent afin de mieux localiser dans l'espace les zones d'obduction et leur continuité, cette thèse s'appuie sur un travail de cartographie, d'analyse structurale, de pétrologie et de datation sur des zones mal étudiées ou en cours d'étude (NE Anatolie et SE de la suture Sevan-Akera).

Ainsi nous cherchons à répondre à trois questions :

- ***Qu'elle est l'ampleur de la nappe obductée au front de la zone de suture ?***

En Arménie la nappe atteint au moins 100 km de portée (Sosson *et al.*, 2010). Mais si les ophiolites de l'Anatolie sont de la même nature géochimique et d'un âge en rapport avec celles du Petit Caucase alors la nappe ophiolitique serait bien plus importante. Elle atteindrait ainsi au moins 200 km de portée. Ce qui en ferait l'une des plus grandes nappes ophiolitiques obductées du globe (à l'affleurement dans une chaîne).

- ***Quelle est la durée de l'obduction ?***

La partie frontale de l'obduction des ophiolites du Petit Caucase est datée entre 90 et 83 Ma (Coniacien-Santonien). Mais on ne sait pas à quel moment s'est initiée l'obduction. Il existe des traces de métamorphisme HT-BP dans la zone de suture près d'Amasia (Arménie) (Aghamalian, 1978), mais ces roches ne nous ont pas encore donné de renseignement précis sur l'âge exact du métamorphisme qui pourrait correspondre à celui d'une semelle d'unité obductée.

- ***Quelle est la (les) cause(s) de l'obduction ?***

Cette question a été soulevée à maintes reprises pour d'autres cas, et l'on admet aujourd'hui que la principale cause est l'accélération de la convergence et /ou l'apparition de panaches mantelliques intra-océaniques ayant pour effet d'augmenter la flottabilité la lithosphère océanique et de conduire à son écaillage pendant la fermeture du domaine océanique. Une autre explication serait l'entrée d'une lithosphère continentale dans une subduction intra-océanique comme l'ont proposé Hafkenschied *et al.* (2006) pour la Téthys au

niveau du Zagros-Oman. Ce processus aurait-il provoqué l'obduction dans le Petit Caucase et en Anatolie ? Ceci est vraisemblable et la nature des ophiolites (tendance géochimique de bassin-arrière arc : Galoyan *et al.*, 2007 ; Rolland *et al.*, 2009 ; Galoyan *et al.*, 2009) et la présence par endroit de roches métamorphiques HP-BT sous ces ophiolites (Rolland et al., 2007) suggère qu'en effet une subduction intra-océanique de type SSZ devait être présente dans l'océan téthysien.

Ensuite pour tester les hypothèses découlant de nos observations, pour vérifier la vraisemblance des réponses que nous fournissons à ces questions et pour de les replacer dans un cadre plus régional, un travail de modélisation numérique sera conduit. Ceci permettra de comprendre les causes du processus d'obduction et plus précisément dans cette région du monde.

<u>Chapitre 2</u> - Etude géologique, pétrogéochimique et métamorphique des ophiolites nord-est anatoliennes et du Petit Caucase : implication géodynamique.

II.1 Article 1 – New structural and petrological data on the Amasia ophiolites (NW Sevan-Akera suture zone, Lesser Caucasus): Insights for a large-scale obduction in Armenia and NE Turkey)

Les ophiolites du Petit Caucase appartiennent à la ceinture ophiolitique nord-téthysienne. Celles-ci représentent la prolongation orientale de la ceinture ophiolitique anatolienne (suture d'Izmir-Ankara-Erzincan) (Knipper, 1975; Knipper & Khain, 1980; Adamia *et al.*, 1981; Şengör & Yılmaz, 1981; Dercourt *et al.*, 1986; Adamia *et al.*, 1987; Ricou, 1994; Yılmaz *et al.*, 2000; Galoyan 2008). Au nord de l'Arménie, cette suture se prolonge par la celle de Sevan-Akera, orientée globalement NW-SE. Elle marque la frontière entre le SAB, au sud, et la marge active de l'Eurasie, au nord. La mise en place d'une marge active de type andin (Somkheto-Karabakh) durant une grande partie du Mésozoïque (Bajocien à Campanien) et de l'Eocène moyen et supérieur témoignerait en faveur d'une subduction plongeant vers le nord sous l'Eurasie (Knipper, 1975; Adamia *et al.*, 1977; Adamia *et al.*, 1981; Maghakyan *et al.*, 1985; Adamia *et al.*, 1987).

Les travaux précédents sur les ophiolites de cette région dans le cadre de la thèse de Galoyan (2008) montrent que les ophiolites arméniennes des zones de Stepanavan, Sevan et Vedi sont toutes de type LOT avec des caractéristiques litho-structurales et pétro-géochimiques identiques (Galoyan *et al.*, 2007; Galoyan, 2008; Rolland *et al.*, 2010; Sosson *et al.*, 2010). De plus, les âges de formation du plancher océanique sont tous compris entre le Jurassique inférieur et moyen. Les datations ont été obtenus par la méthode $^{40}Ar/^{39}Ar$ sur amphiboles de gabbro de Sevan et de diorite de Vedi, donnant respectivement 165,3 ± 1,7 Ma et de 178,7 ± 2,6 Ma (Galoyan *et al.*, 2009; Rolland *et al.*, 2010). Ces datations radiochronologiques sont confirmées par les assemblages de radiolaires reconnues dans ces zones (Danelian *et al.,* 2000; 2008; 2012; Asatryan *et al.*, 2009; 2010)

Le massif ophiolitique d'Amasia est situé à 5 km NW de la ville Amasia dans le prolongement ouest de la zone de Sevan-Akera. Sur une surface de ~30 km^2 affleurent des peridotites et pyroxénites serpentinisées, des gabbros et plagiogranites (en filons d'une épaisseur de 1cm à 1m), des radiolarites, des basaltes ainsi que des roches métamorphiques (amphibolites à grenat : Sokolov, 1974; Aghamalyan, 1998). Tatevosyan (1950) décrit des

gabbros au nord et des roches volcaniques Turoniennes au sud. Toujours d'après Tatevosyan (1950), ces roches volcaniques recouvrent en discordance des schistes et sont surmontées par des calcaires du Crétacé supérieur. Les roches ultrabasiques et gabbroïques du massif ophiolitique d'Amasia ont déjà fait l'objet d'études montrant que les péridotites sont parfois fortement serpentinisées. Toutefois, malgré cette serpentinisation il est toutefois possible de reconnaître qu'il s'agit de lherzolites (Tatevosyan, 1950).

Sur la base de directions structurales différentes, certains auteurs ont proposé que les ophiolites Sevan-Akera et Stepanavan-Amasia proviendraient de différents segments de croûte océanique (Melikyan, 2004). Afin de valider l'hypothèse de Galoyan (2008) concernant la présence d'une seule et même nappe ophiolitique obduite à l'échelle du SAB, et donc afin de lever l'ambigüité concernant l'appartenance, et donc la continuité, du massif ophiolitique d'Amasia à la suture Sevan-Akera, nous avons effectué une étude pétro-structurale incluant des datations $^{40}Ar/^{39}Ar$ de ce massif.

Notre cartographie a mis en évidence une série comprenant (1) de la croûte océanique gabbroïque non métamorphisée, (2) des serpentinites, (3)mélange tectonique de faciès schiste vert composé basaltes en coussins déformés avec des radiolarites intercalées, et (4) une écaille basale d'amphibolites à grenat. Cette semelle métamorphique montre des caractéristiques géochimiques similaires à celles de l'ophiolite. Ces unités sont découpées par des failles inverses et déformés par des phases post-Eocène de compression de la zone de suture au cours de, et après, la collision du SAB avec l'Eurasie. Les datations $^{40}Ar/^{39}Ar$ sur les amphiboles des gabbros ont donné des âges de 169,0 ± 4,6 à 175,8 ± 3,9 Ma.

L'ensemble de ces âges ainsi que les compositions des roches ophiolitiques sont similaires à ceux des autres ophiolites arméniennes et de celles de Turquie du NE. Aussi, toutes ces données sont donc bien en accord avec la mise en place d'une seule nappe ophiolitique à l'échelle de l'Anatolie du NE et de l'Arménie au début du Crétacé supérieur (c. 90 Ma). Ces résultats suggèrent également que l'ensemble du domaine obduit provient d'un domaine où la croûte océanique formée est contaminée par la subduction. Il pourrait s'agir d'un bassin arrière-arc, ou d'une zone surplombant la subduction. Ce bassin se serait ouvert au Jurassique, puis obduit par la suite sur le SAB-TAP.

Cette étude a fait l'objet d'une publication parue dans *Tectonophysics*.

Abstract

The ophiolites of Amasia in the northwestern part of the Sevan-Akera suture zone (Lesser Caucasus, NW Armenia) correspond to a well-preserved example of a major obduction of oceanic lithosphere over the South Armenian continental block. Our mapping evidenced a series of (1) un-metamorphosed gabbroic oceanic crust, (2) serpentinites and a greenschist grade tectonic melange composed of deformed pillow-basalts, radiolarites and cherts, and (3) a basal slice of garnet amphibolites bearing similar compositional features as the ophiolite. These units are sliced and deformed by post-Eocene thrusting related to the shortening of the suture zone after the collision of the South Armenian Block with Eurasia. $^{40}Ar/^{39}Ar$ dating on gabbro amphiboles yielded ages of 169.0 ± 4.6 to 175.8 ± 3.9 Ma. This age and geochemical composition of ophiolite rocks are similar to those of other ophiolite outcrops in Armenia and NE Turkey. Structural and geochemical analyses undertaken on the garnet amphibolites suggest it to represent the obducted ophiolite metamorphic sole. All these data are in agreement with the presence of a unique ophiolite nappe at the scale of NE Turkey-Armenia originating from a Jurassic intra-oceanic back-arc basin, obducted onto the Armenian-Taurides-Anatolides microblocks in the early Late Cretaceous (c. 90 Ma).

Keywords : Ophiolites; $^{40}Ar/^{39}Ar$; Lesser Caucasus; Armenia; Amasia; Izmir-Ankara-Erzincan-Sevan suture

1.1 Introduction

In order to better understand the different phases linked with the opening and closing of the Tethyan Ocean leading to the current structure of the Lesser Caucasus, it is important to identify the different units involved in the Tethyan paleosuture *s.l.* and their corresponding geodynamic context. The evolution of central and northern Neotethys can be deduced from both the geochemical and geochronological study of preserved oceanic crust domains obducted (ophiolites) in the Lesser Caucasus and the metamorphic rocks beneath ophiolites. These studies yield key time and palaeogeographic data from the East Mediterranean area to the NW Himalayan belt (Sengör and Yılmaz, 1981; Ricou et al., 1985; Dercourt et al., 1986; Ricou, 1994; Okay and Tüysüz, 1999; Stampfli et al., 2001; Robertson et al., 2004; Barrier and Vrielynck, 2008; Galoyan et al., 2009; Rolland et al., 2010; Sosson et al., 2010). Ophiolites provide constraints on oceanic opening by the dating of related magmatic rocks and of its closure by the dating of metamorphic rocks and post-accretionary sedimentary complexes unconformably overlying the suture zone. Datings undertaken along the Ankara-Erzincan-Sevan suture zone suggest a similar Lower-Middle Jurassic age of the oceanic crust (Çelik et al., 2011; Galoyan, 2008; Galoyan et al., 2009; Rolland et al., 2009b; 2010). A major difficulty in the Lesser Caucasus Mesozoic geodynamic reconstruction lies in the paucity of outcrops due to thick post-obduction (Eocene to Quaternary) deposit of sediments and volcanites over the ophiolitic nappe (Sosson et al., 2010). Therefore, to link the NE Turkey and Armenia ophiolitic domains, one of the main questions posed in this study is the origin of the ophiolite: “are all the NE Turkey-Armenia ophiolites remnants of the same oceanic lithosphere, obducted over the Armenian-Tauride-Anatolide Block?”

In this paper is reported new geological, petrologic and $^{40}Ar/^{39}Ar$ chronological data obtained on the Amasia ophiolite (NW Armenia) which strongly suggests a common origin with the other Armenian ophiolites (Sevan, Stepanavan and Vedi ophiolites) and NE Turkey (Refahiye, Şahvelet, Karadağ and Kırdağ).

1.2 Geological context

During the Mesozoic, the Southern margin of the Eurasian continent was involved in the closure of the Paleotethys and opening Neotethys Ocean (Adamia et al., 1981). Later, from the Jurassic to the Eocene, subductions, obductions, micro-plate accretions, and finally continent–continent collision occurred between Eurasia and Arabia, and resulted in the closure of Neotethys (Sosson et al., 2010; **Figure 7**).

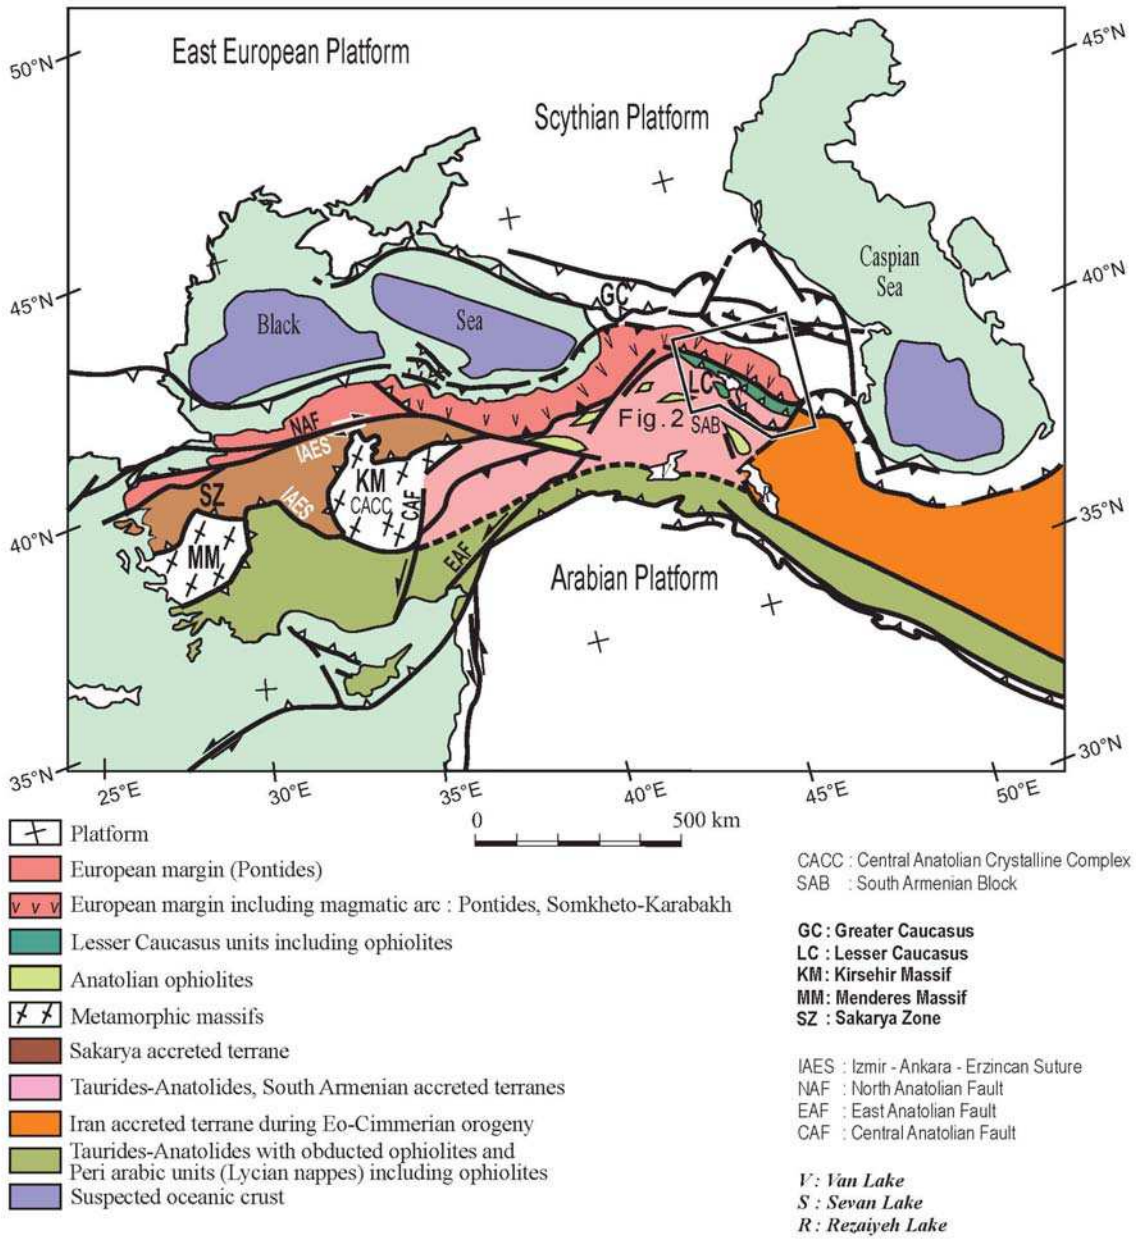

Figure 7 - Tectonic map of the Middle East–Caucasus area, with main blocks and suture zones, after Avagyan et al. (2005), modified. Location of figure 8 indicated.

The study of Armenian ophiolites allows reconstructing part of this complex history. Previous geological, petrological and geochemical works on these ophiolites were carried out mostly during the 1970's and 1980's (Knipper, 1975; Sokolov, 1977; Knipper and Sokolov, 1977; Knipper and Khain, 1980; Adamia et al., 1981; Zakariadze et al., 1983, 1990; Knipper et al., 1986; Knipper et al., 1997; Satian, 2005; Zakariadze et al., 2005). These works showed a mainly Jurassic age for the ophiolite bodies, with varied geochemistry (from tholeiitic to calc-alkaline and alkaline), which was interpreted as a complex oceanic context with varied

magmatic sources closed by subduction in the Late Cretaceous. More recent works (Hacker, 1991; Yilmaz et al., 1993; Hacker et al., 1996; Harper et al., 1996; Searle and Cox, 1999; Okay et al., 2001; Stampfli et al., 2001; de Sigoyer et al., 2004; Ding et al., 2005; Galoyan et al., 2009; Rice et al., 2009; Rolland et al., 2009a-b; 2011a-b; Agard et al., 2010; Sosson et al., 2010) evidence processes which include Neotethyan oceanic crust obduction and the collision–accretion of microplates to the Eurasian margin before the final Arabia–Asia collision.

North of the obduction zone, in the Eurasian part of the Lesser Caucasus the subduction of the Tethys is evidenced by a thick and mainly calcalkaline volcanogenic and volcanoclastic series dated as Bajocian to Santonian (e.g. Adamia et al., 1981 for a review). At this period of time the northern Lesser Caucasus was characterized by an island arc domain called the Somkheto-Karabakh Island Arc (Knipper, 1975; Adamia et al., 1977; 1987; Ricou et al., 1986; Sosson et al., 2010). During the Early Cretaceous an active erosion event took place, which resulted in the unroofing of plutons of the magmatic arc. This erosion event is the result of significant uplift and denudation during the Early Cretaceous. The reasons for such a change in the Eurasian active margin strain field could be the subduction of the spreading ridge of the back-arc basin. The basement formations are quite similar to those known all along the Eurasian margin (Sosson et al., 2010 for a review).

The Eastern Pontides are interpreted as a part of the Sakarya Zone (Okay and Şahintürk, 1997) They represent an active continental margin of Eurasia, which was formed as result of northward subduction of Neotethys during Late Cretaceous (Şengör and Yılmaz, 1981; Akıncı, 1984; Okay and Şahintürk, 1997; Parlak et al., 2012). There is no consensus concerning onset of subduction since Jurassic (Adamia et al., 1981; Hess et al., 1995; Nikishin et al., 2003), Cenomanian-Turonian (Yılmaz et al., 1997; Okay and Şahintürk, 1997) or Albian (Okay et al., 2006) ages have been proposed. The lack of consensus equally stands when considering the end subduction and continental collision; end of Eocene (Peccerillio and Taylor, 1976; Şengör and Yılmaz, 1981; Robinson et al., 1995), Middle Eocene (Yılmaz et al., 1997) or Paleocene (Okay and Şahintürk, 1997) have been proposed.

South of the obduction zone, the South Armenian Block (SAB) (Knipper, 1975; Knipper and Khain, 1980) is a microplate also corresponds to the Turkish and Iranian platform (Sengör and Yılmaz, 1981; **Figure 7**). In Armenia the SAB is represented by a Proterozoic metamorphic basement well exposed north of Yerevan, an incomplete Palaeozoic sedimentary succession (mainly represented by Upper Devonian to Upper Permian carbonates

and shales) in the SW (north of the Araks Valley), Triassic limestones and sandstones and some Jurassic sedimentary and volcanogenic formations, Cenomanian to Turonian limestone and flysch (Nalivkin, 1976; Sosson et al., 2010) (**Figures 8** and **9**).

The East Anatolian Platform (EAP) represents a continental platform between the northern and southern branches of Neotethys (Bozkurt and Mittwede, 2001). As the SAB, the EAP represents a sliver of continental crust having rifted off northern Gondwana and drifted north to collide with Eurasia (Stocklin, 1974; 1977; Adamia et al., 1977; Biju-Duval et al., 1977; Dercourt et al., 1986; Şengün, 2006).

Upper Cretaceous obduction on the SAB is deduced from Upper Coniacian to Santonian flysch (reworking the ophiolites), which conformably covers Cenomanian-Turonian reef limestones and flysch of the SAB (Sokolov, 1977; Sosson et al., 2010; **Figure 9**). Obduction took place while a magmatic arc occurred along the southern edge of Eurasia (Somkheto-Karabagh island arc, Lesser Caucasus; Eastern Pontides arc, Anatolia; **Figure 7**), which implies that at least two subduction zones were active at the same time (Rolland et al., 2011a). The onset of collision or the continental subduction of the SAB below the Eurasian margin is dated as Late Cretaceous-Paleocene. This process occurred around 20 Ma later than the obduction (Late Coniacian–Santonian, 88–83 Ma) of the marginal basin over the SAB (Sosson et al., 2010). Oceanic closure is indicated by the late-Middle Eocene unconformity on the SAB, the suture zone and the Eurasia margin. Ending of subduction and subsequent accretion of the SAB to the Eurasian margin results in subduction jump to the south of the SAB and related Tauride-Anatolide Block(s) (TAB) in the same period of time. Evidence for this southward jump in subduction can be found between the Bitlis-Pütürge massifs and SAB. A HP metamorphic evolution bracketed between 74-71 Ma (Göncüoğlu and Turhan, 1984; Hempton, 1985; Oberhänsli et al., 2010). The metamorphic age is in agreement with a continental subduction event that occurred before final closure of the southern Neotethys and Arabian-Eurasian collision. $^{40}Ar/^{39}Ar$ dates agree for initial subduction of the Eastern Bitlis massif at 74 Ma followed by underthrusting of the Pütürge massif under blueschists conditions at 71 Ma (Rolland et al., 2012).

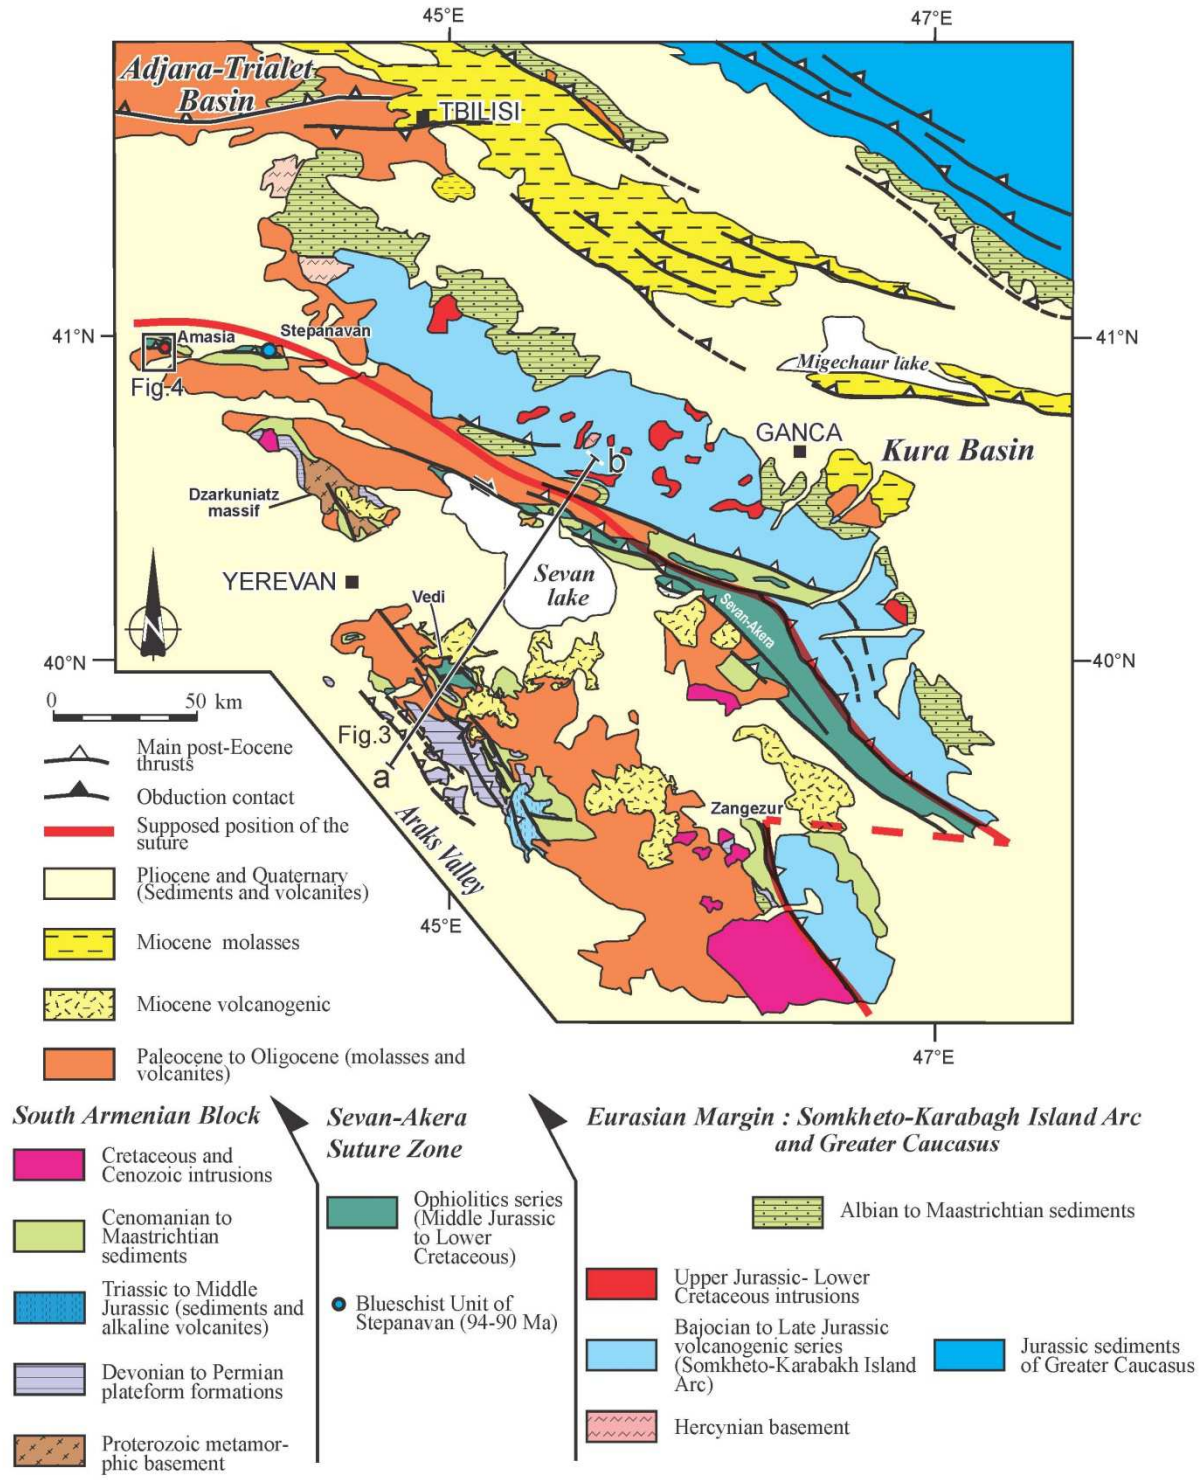

Figure 8 - Structural map of the Lesser Caucasus modified from Sosson et al. (2010). Location is indicated on figure 7. Plot of geological section figure 9 and location of figure 10 indicated.

For a compilation of works about the ophiolites of the Lesser Caucasus, the reader is referred to Galoyan et al. (2007, 2009) and Rolland et al. (2009b). These authors have shown the following geochemical tendencies in the ophiolite-related nappes: (1) the basalts and gabbros mainly bear an enriched tholeiitic composition, contaminated by subduction

components, (2) above these series, a layer of alkaline basalt lava flows with large pillows is supposed to represent Ocean Island Basalts (OIB) erupted in seamounts or oceanic plateau(s), (3) locally some arc-related basalts have been described. In Armenia, the oceanic gabbros of the tholeiitic series are dated to 170-150 Ma similar to radiolarian ages (Danelian et al., 2010), while the alkaline series were dated at c. 117 Ma (Rolland et al., 2009b).

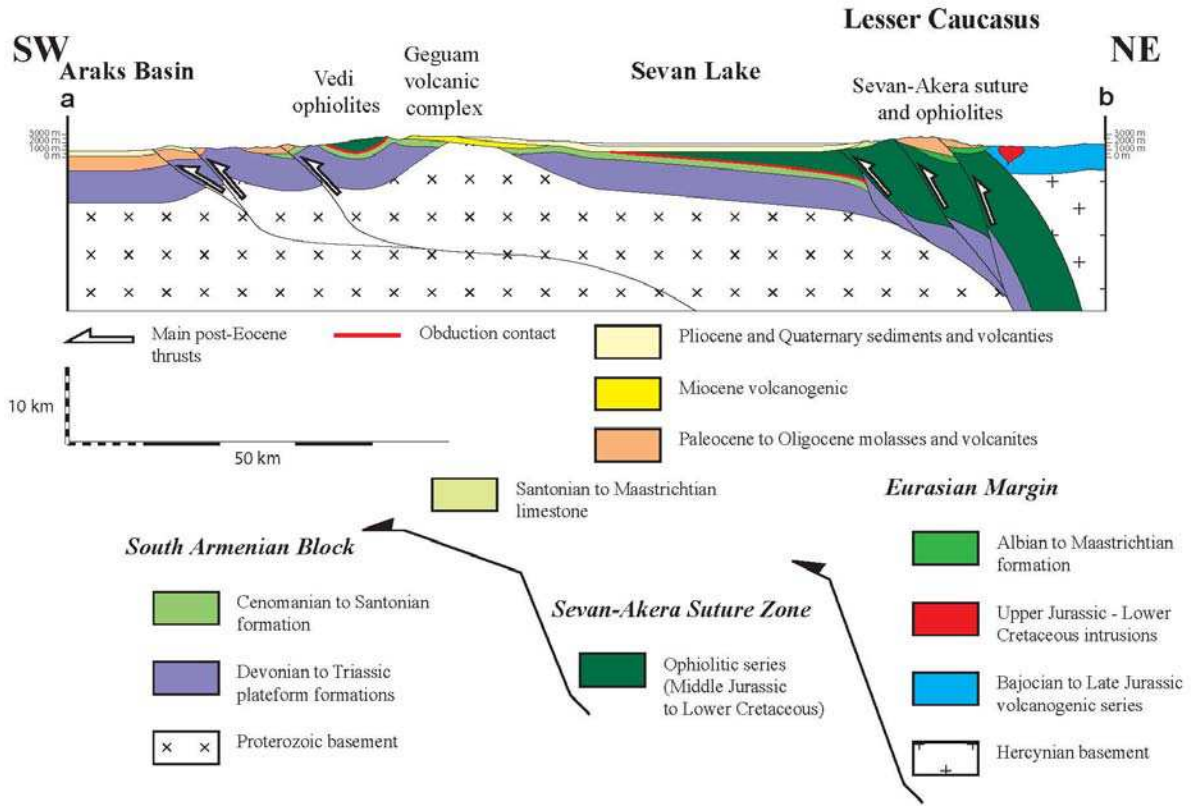

Figure 9 - Interpretative crustal-scale sketch cross-section of the Armenian-Azerbaijan transect. Location is indicated on Figure 8.

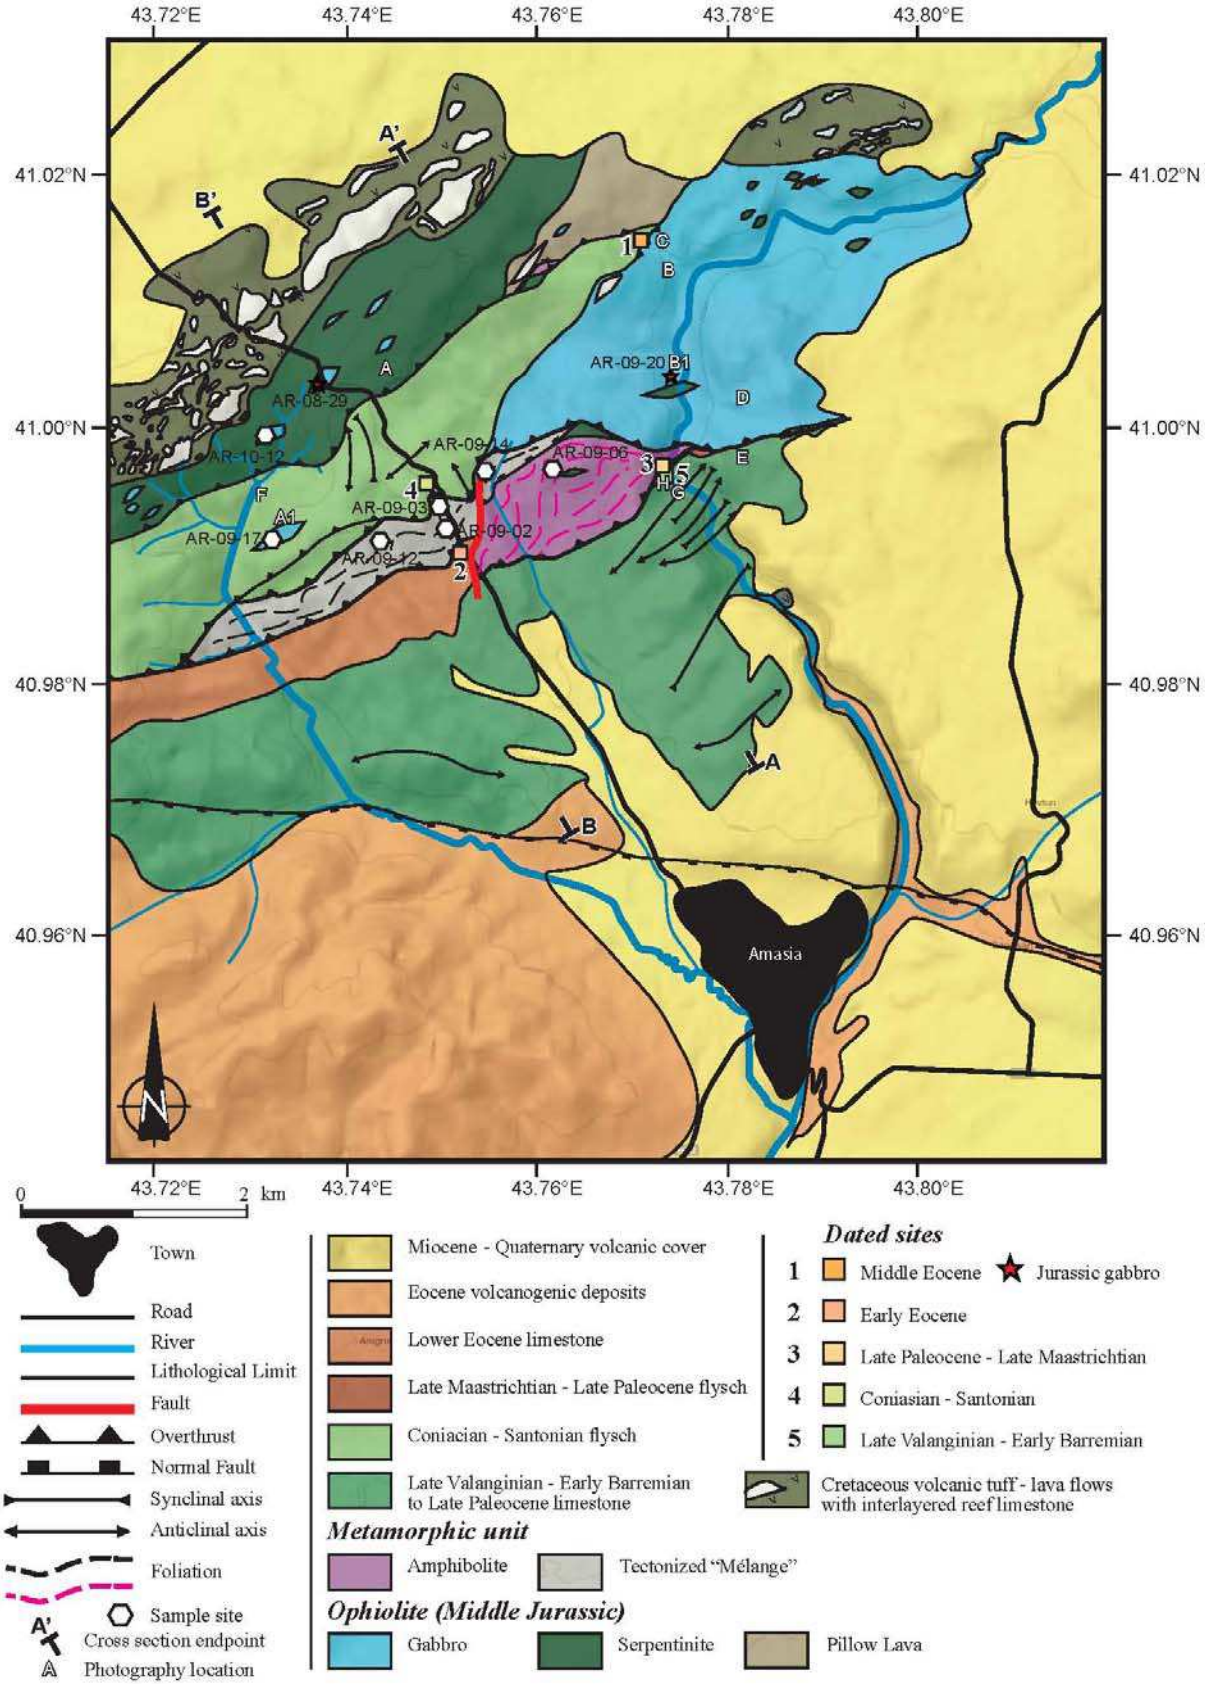

Figure 10 - Structural map of the Amasia ophiolite window. Location is indicated on figure 9. Plot of geological sections of figure 11 along with dated samples by the Ar-Ar method and paleontological identification are shown.

The Amasia ophiolite is aligned within the Lesser Caucasus ophiolite belt (Amasia-Sevan-Akera ophiolites), striking SE–NW in northern Armenia (**Figure 9**), generally interpreted as representing the suture zone (e.g., Zakariadze et al., 2007) between Eurasia and the SAB. In Stepanavan, East of Amasia, ophiolites have been described in association with blueschists and amphibolite facies metamorphic rocks dated at 94-91 Ma (Pressure peak) to 73-71 Ma (High temperature retrogression; Rolland et al., 2009a). These metamorphic rocks evidence the presence of a subduction zone active at least in the Middle Cretaceous and closing in the Late Cretaceous at 80-75 Ma (Rolland et al., 2011a).

1.3 Field and sample observations

According to the field observations and the new geological map with cross sections we have made (**Figure 10** and **12**), 3 main lithotectonic units have been identified (from top to bottom) (**Figure 11**);

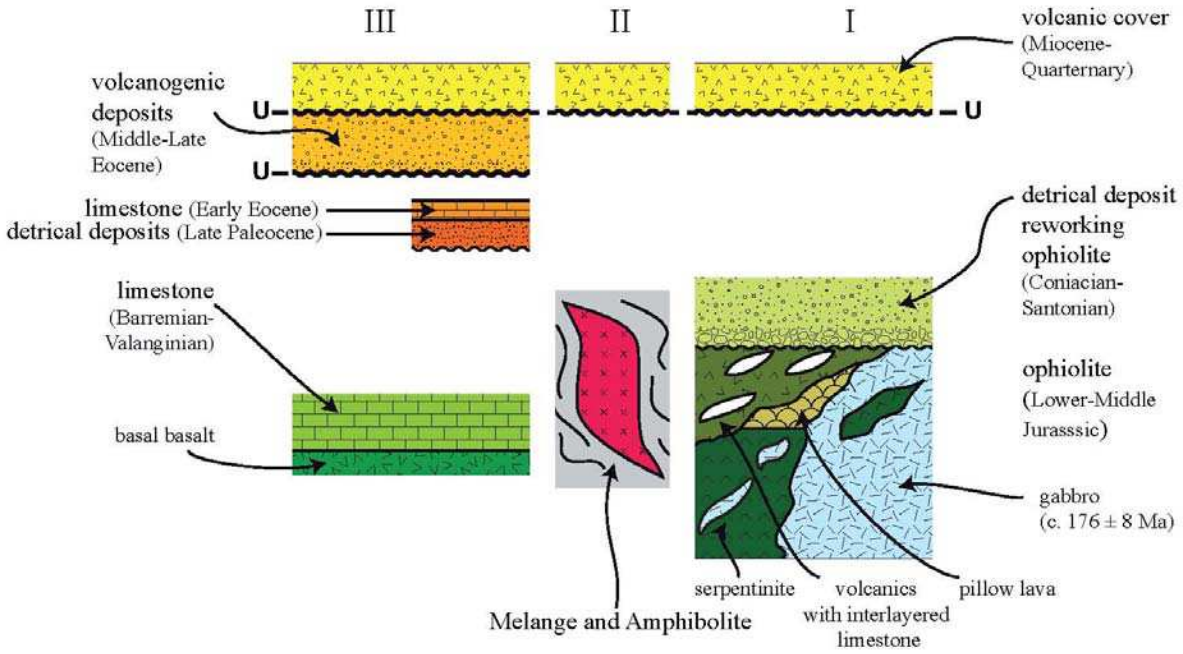

Figure 11 - Synthetic lithostratigraphic log of the three main units of the Amasia ophiolite window. I, the upper unite corresponding to ophiolite. II, the metamorphic unit comprising of the tectonic melange and the lens of garnet bearing amphibolites. III, the lower unit.

1 - An upper unit (ophiolites) with serpentinite, gabbro, pillow lava and volcanic rocks with interlayered reef limestone. Included in this unit a Coniacian-Santonian detrical deposit, reworking elements from the entire ophiolitic unit.

2 - A tectonic melange of low grade (greenschist facies) meta-basalt, meta-chert and metamorphosed serpentinite which includes lenses of ophiolite and a major garnet bearing amphibolites unit,

3 - A lower unit of basal basalts, overlain by Valanginian-Barremian limestones, which are in turn unconformably covered by late Paleocene flysch to Lower Eocene limestone as well as Mid- to Upper Eocene volcanogenic deposits (as in all of the Lesser Caucasus) (Sosson et al., 2010).

All of these units are unconformably overlain by a Miocene to Quaternary volcanic cover.

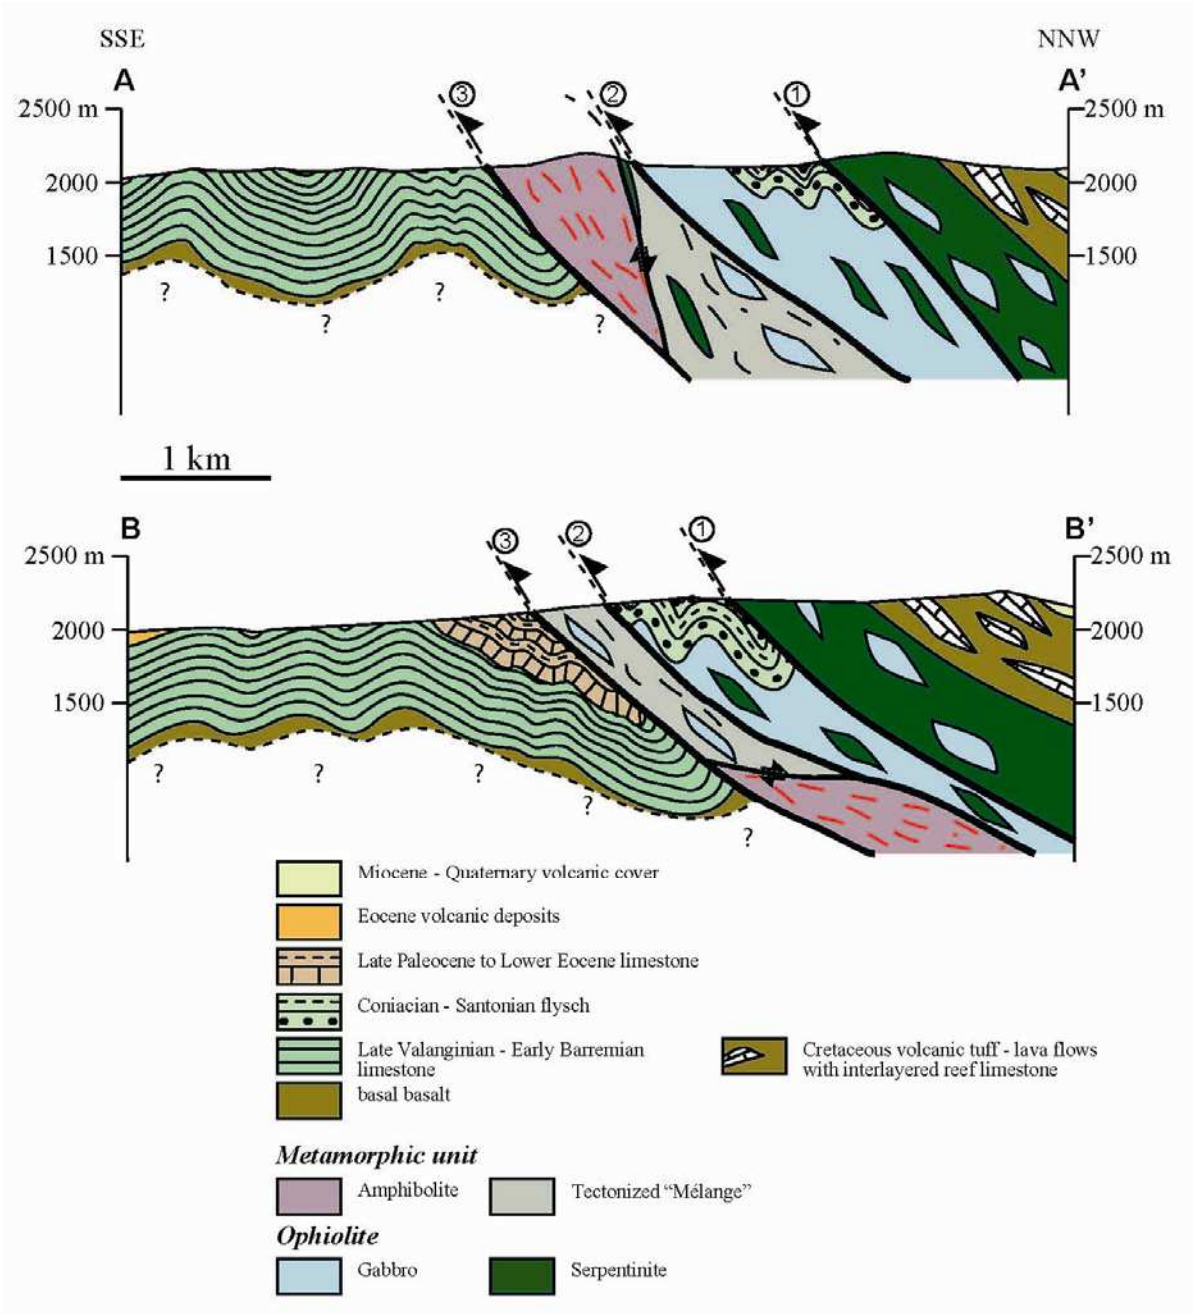

Figure 12 - Sketch geological cross sections of Amasia ophiolite. Locations are indicated on figure 10.

1.3.1 The upper unit (ophiolite)

The northern part of the map corresponds to an ophiolitic series (upper unit) generally dipping towards NNW. Sampling for dating of formation and characterization was undergone in this unit (**Figure 10**). It is composed, from top to bottom, of interbedded reef limestones embedded in volcanic tuffs and lava flows of supposed Cretaceous times, serpentinites comprising lenses of gabbros, scattered outcrops of volcanic rocks, and gabbros with punctual lenses of serpentinites (**Figure 13A**). These volcanics are linked to arc related volcanism and erosion, including possible OIB volcanism deposited on the seafloor prior to obduction. The lenses of gabbros in the serpentinites are generally well preserved and show a WSW-ENE stretching direction. These lenses are also penetrated by dikes of acidic composition (plagiogranite) and quartz veins. The outcrops of serpentinite in the gabbro do not have neatly defined contacts but appear in patches suggesting a gradational transition from the gabbro, in agreement with a cumulative origin. The northern contact of the gabbro with the serpentinites is deduced by a greater number of outcrops of serpentinites, multi-centimetric amphiboles and an increase in dike thickness and density approaching the contact zone. It is masked by Coniacian-Santonian flysch. Thus, the tectonic intercalation nucleates on previous ocean-floor faults, which illustrates the role of previous anisotropies in the obduction tectonics (**Figure 13B** and **13C**).

A syn-tectonic detrital deposits reworking elements of the ophiolite rests unconformably on top. Along the northern limit of the outcrop it is overthrusted by serpentinite (upper ophiolitic unit) towards the south (**Figure 13F**). Its southern limit is characterized by deformation by thrusting and scaling onto the metamorphic unit. Its nannofossil age (**Table 4**) is bracketed to the Coniacian-Santonian (89.3-83.5 Ma). The deformation consequent to this thrust is marked by dissymmetrical folds, with axes aligned with the general strike of the thrust. This fault, characterized by a NNW dip, was subsequently active during or after the deposit of this detrital material, i.e. syn-post Coniacian (89 Ma). Laterally to the east, this formation is unconformably lying along on gabbro. At its extreme NE limit with the gabbro, the detrital deposits are overthrusted by the gabbros along a fault contact with a SE dip.

1.3.2 The tectonic melange

Underneath this ophiolitic series, there is a tectonic melange made of serpentinites, gabbros, basaltic lavas and metasediments. Most of the sampling was undergone in this unit (**Figure 10**). This melange represents relics of the oceanic domain underthrusted throughout obduction initiation and the intraoceanic part of the obduction process (Gaggero et al., 2009). The limestone blocks which are incorporated in this level are morphologically arranged in discontinuous lenses stretched out with the surrounding rock, which locally present boudinage. This deformation is in agreement with NNE-SSW shortening and with general top to the south sense of shear. Tectonically below this low-grade tectonic unit, to the East, there is a large (≈ 2 km²) outcrop of garnet-bearing amphibolite (**Figure 13D**).

The outcrop of amphibolites also has a lens shape and is also elongated in an ENE-WSW direction. A penetrative foliation is marked by an alternation of amphibole rich dark levels and mica-, garnet- and quartz-rich, red or white levels. The alignment of the amphiboles, chlorites and phengites, along with the presence of rolled garnets evidence**s** that the amphibolite massif was tectonized with top to the south sense of shear. Locally within this unit some highly strained lens shaped serpentinite inclusions are observed, which present an ENE-WSW stretching direction.

Two stages of metamorphism have been identified in the amphibolites, comprising (1) a High Temperature (HT) paragenesis in the amphibolites facies (hornblende-plagioclase-garnet), and (2) a retrogressive Greenschist facies paragenesis (chlorite-epidote-albite).

1.3.3 The lower unit

The third unit of the studied area is characterized by Cretaceous limestone unconformably overlying basalts.

The limestone outcrops are very weathered and present important folding and fracturing. The stratification is well marked and depicts various folds with axes generally

oriented NE-SW. The folding of the limestone increases as it dips north under the tectonic melange, approaching the contact with the flysch and the major tectonic contact at the base of the amphibolites. The stratification of the limestone dips to the north, under the amphibolite massif (**Figure 13E**).

Extremely deformed detrital deposits are found in stratigraphic contact unconformably on top of the Valanginian-Barremian limestone (**Table 4**). This unit shows a sedimentary contact with the limestone further to the south. This sedimentary basin locates, with its northern limit, a major thrust. This north-dipping fault throws the tectonized melange and the ophiolite on top of the flysch. Paleontological datings (**Table 4** and **Figure 10**) show Maastrichtian-Campanian (83.5-65.5 Ma) ages in the flysch series evolving to Lower-Eocene (< 40.4 Ma) ages in the limestones to the West. The flysch deposits are highly deformed by thrust faulting and related dissymmetrical folding (**Figure 13G**). The Lower Eocene series is better preserved, the stratification is slightly deformed, showing little faulting and folding. Its northern contact features sub-vertical dipping below the major thrust (**Figue 13H**).

1.4 $^{40}Ar/^{39}Ar$ Dating

1.4.1 Analytical procedures

1.4.1.1 Electron microprobe analysis

Mineral compositions were determined by electron probe microanalysis (EPMA). The analyses are presented in **Table 1**. They were carried out using a Cameca Camebax SX100 electron microprobe at 15 kV and 10 nA beam current, at the Blaise Pascal University (Clermont-Ferrand, France). Natural samples were used as standards.

1.4.1.2 $^{40}Ar/^{39}Ar$ analysis

Geochronology was undertaken by laser $^{40}Ar/^{39}Ar$ dating of amphiboles. Results are presented in **Table 3** (detailed results may be found in **Annexes 2** and **3**). The amphiboles were analyzed by EPMA prior to dating in order to check mineral composition homogeneity. Grains between 800 μm and 500 μm were separated by careful selection by hand-picking under a binocular microscope to prevent the presence of altered grains. The samples were then irradiated in the nuclear reactor at McMaster University in Hamilton (Canada), in position 5c, along with Hb3gr hornblende neutron fluence monitor, for which an age of 1072 Ma is adopted (Turner et al., 1971). The total neutron flux density during irradiation was 9.0×10^{18}

neutron cm^{-2}. The estimated error bar on the corresponding $^{40}Ar^*/^{39}Ar_K$ ratio is ± 0.2% (1r) in the volume where the samples were set. All $^{40}Ar/^{39}Ar$ measurements were undergone in the University of Nice-Sophia Antipolis (UMR 7329 Géoazur). Analyses of amphibole grains were undertaken by step heating with a 50 W CO2 Synrad 48-5 continuous laser beam. Measurement of isotopic ratios was done with a VG3600 mass spectrometer equipped with a Daly detector system. Detailed procedures are described in Jourdan et al. (2004). The typical blank values for extraction and purification of the laser system are in the range 4.2–8.75, 1.2–3.9, and 2–6 cc STP for masses 40, 39 and 36, respectively. Mass discrimination was monitored by regularly analyzing air pipette volumes. Decay constants are those given by Steiger and Jäger (1977). Uncertainties on apparent ages are given at the 2σ level and do not include the error on the $^{40}Ar^*/^{39}Ar_K$ ratio of the monitor. The criteria generally used in the laboratory for defining a ‘‘plateau’’ age are the following: (1) it should contain at least 70% of total ^{39}Ar released; (2) there should be at least three successive step-heating fractions in the plateau; (3) the integrated age of the plateau (weighted average of apparent ages of individual fractions comprising the plateau) should agree with each apparent age of the plateau with a 1σ error.

1.4.2 Results

The gabbro samples, AR-09-20 (**Figures 14 1A** and **14 1B**) and AR-08-29 (**Figures 14 2A** and **14 2B**), were sampled from massif and well preserved outcrops. Plateau ages (**Table 3**; **Figures 15 1a** and **15 2a**) were obtained after analysis of a single amphibole grain for each sample. Considering the homogeneous distribution of Ca/K values during the experiments (**Figures 15 1b** and **15 2b**) and EPMA analysis (**Figure 16**), only one mineral phase has contributed to the Ar-Ar signal in each sample.

The amphibole from the sample AR-09-20 gave a plateau age of 169.0 ± 4.9 Ma with a good MSWD of 1.46. This age was calculated using the last six heating steps representing 97.3 % of the total ^{39}Ar gas freed during the whole analysis. The inverse isochron age acquired is 171.7 ± 3.9 Ma with a good MSWD of 0.85, in accordance with the plateau age. Furthermore, this representation allows the validation of this age as the $(^{36}Ar/^{40}Ar)_0$ value is of 262 ± 30.2), which is close to the air value (295).

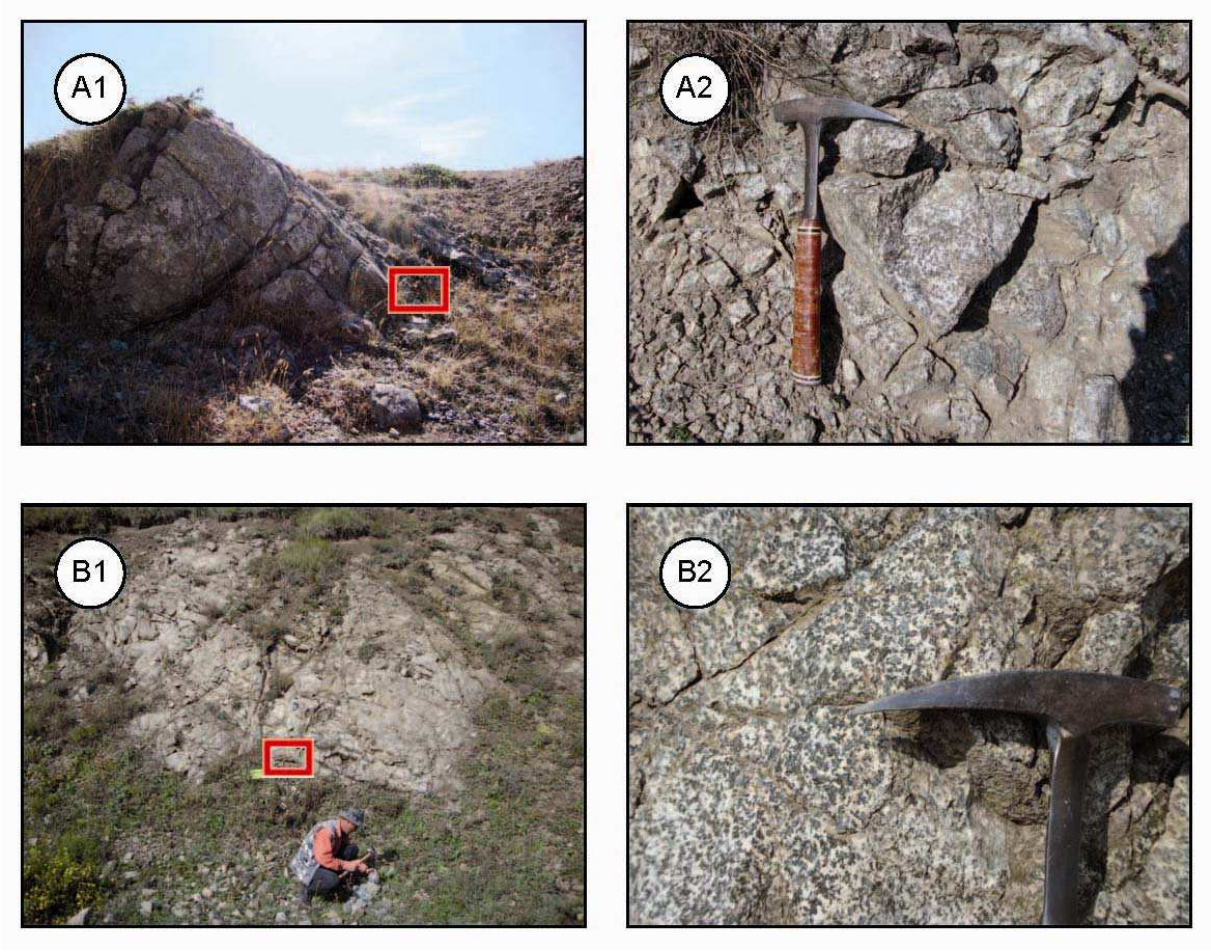

Figure 14 - Representative field photographs of dated gabbro sample outcrops. Photos "A" are of AR-08-29 and photos "B" are of AR-09-20.

The amphibole from the sample AR-08-29 gave a plateau age of 175.8 ± 3.9 Ma with a good MSWD of 0.98. This age was calculated using the last five heating steps representing 98.1 % of the total ^{39}Ar gas freed during the whole routine. The inverse isochron age acquired is 178.6 ± 5.4 Ma with a similar MSWD of 0.98, in accordance with the plateau age. The $(^{36}Ar/^{40}Ar)_0$ is also close to the present air value.

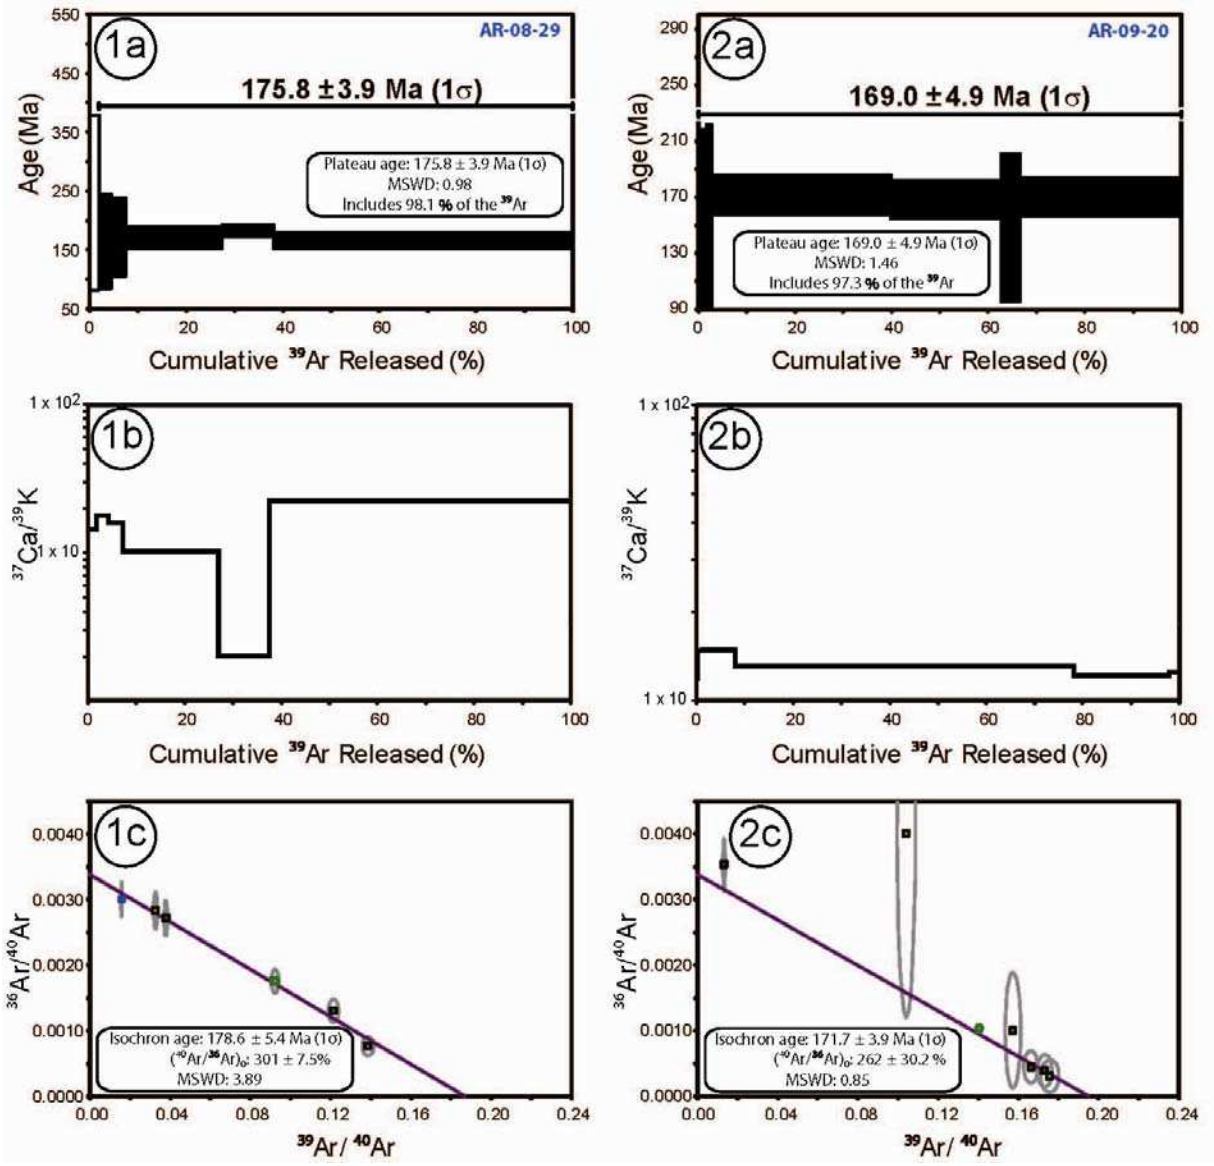

Figure 15 - $^{40}Ar/^{39}Ar$ age spectra Ca/K spectra and inverse isochrones of gabbro amphiboles. Locations of samples are shown on figure 10.

In conclusion, the two gabbro amphibole Ar-Ar ages agree with a crystallization age during oceanic crust formation at about 169-176 Ma, at the end of the Lower Jurassic (Toarcian), in agreement with other datings obtained in Armenian ophiolites (Galoyan et al., 2009; Rolland et al., 2009b).

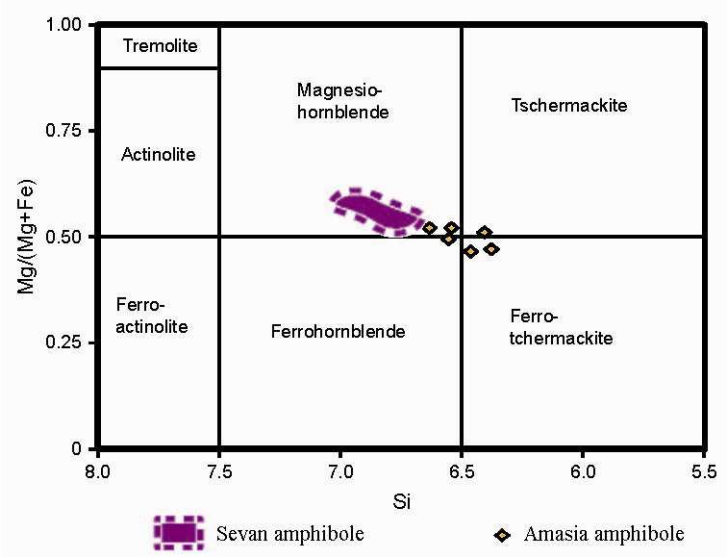

Figure 16 - Chemical composition of amphibole from the AR-08-21 and AR-08-22 gabbro samples, after Leake et al. (1997). Data concerning Sevan amphiboles from Galoyan et al. (2009).

1.5 Geochemistry

1.5.1 Analytical procedures

Samples from the Amasia ophiolite and related metamorphics were analyzed for elements major, trace and Rare Earth Elements (REE; **Table 2**). Samples were analyzed at the C.R.P.G. (Nancy, France). Analytical procedures and analyses of standards can be found on the following website (http://www.crpg.cnrs-nancy.fr/SARM).

The sampling was undertaken during three field work campaigns in 2008, 2009 and 2010. Additional data pertaining to the other Armenian ophiolites along with the Turkish ophiolites are published in Galoyan (2008) and Parlak et al. (2012), respectively. In order to designate rock groups, trends and tectonic environments (Pearce and Cann, 1973; Floyd and Winchester, 1975; 1978; Pearce and Norry, 1979; Pearce, 1982; 1983; 1996) the option to study the relatively immobile elements, such as Ti, Zr, Y, Nb, Ta, Th, V and REEs, was chosen since the immobility of these elements during low grade submarine alteration is constrained in a number of studies (e.g. Hart et al., 1974; Humphris and Thompson, 1978) (**Figures 17** and **18**). Chondrite normalized REE plots and Normal Mid Oceanic Ridge Basalt (N-MORB) normalized spidergrams for the Turkish and Armenian ophiolites are presented in **Figures 19** and **20**, respectively. We analyzed two types of rocks: (1) magmatic rocks (basalt, gabbro and plagiogranite) from the ophiolite unit and (2) metamorphic rocks (amphibolites) from the metamorphic sole. In Amasia, considering the geochemical data obtained from samples of the ophiolites and related metamorphic rocks, two tendencies are well observed.

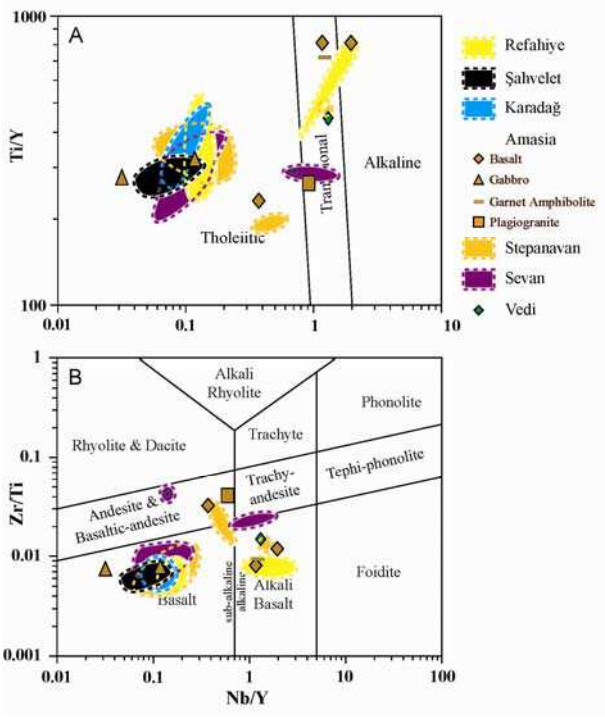

Figure 17 - Diagrams for crustal rocks of the ophiolites. Data concerning Erzinncan-Erzurum region (Refahiye, Şahvelet and Karadağ) from Parlak et al. (2012) and concerning Stepanavan, Sevan and Vedi from Galoyan et al. (2007; 2009) and Rolland et al. (2009b; 2010). A, Ti/Y versus Nb/Y (after Pearce 1982). B, Zr/Ti versus Nb/Y (after Pearce 1996).

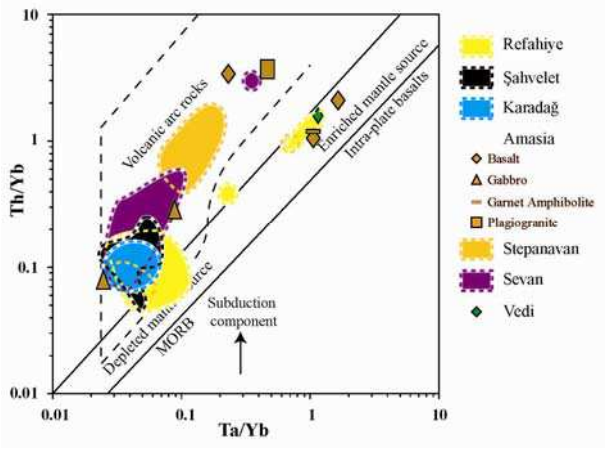

Figure 18 - Ta/Yb versus Th/Yb diagram (after Pearse 1982) for crustal rocks of the ophiolites. Data concerning Erzinncan-Erzurum region (Refahiye, Şahvelet and Karadağ) from Parlak et al. (2012) and concerning Stepanavan, Sevan and Vedi from Galoyan et al. (2007; 2009) and Rolland et al. (2009b; 2010).

1.5.2 Supra-subduction tholeiitic signature

A tholeiitic (MORB-type) affiliation is found for the gabbro samples with some fertile contamination. Ti/Y vs. Nb/Y and Zr/Ti vs. Nb/Y diagrams plot these samples as basaltic tholeiitic composition (**Figure 17**). The trace element patterns show generally marked negative anomalies in Ta-Nb and enrichment in Large Ion Lithophile Elements (LILE) (**Figures 19** and **20**). This variable enrichment can be explained by different degrees of fractional crystallization, as exemplified by increasing enrichments in all trace elements in the plagiogranite, with respect to gabbros., except for the negative Eu and Ti anomalies exhibited in this most differentiated rock, which is ascribed to plagioclase and amphibole/titanite fractionation, respectively. Indeed, the gabbros have rather flat spectra while the plagiogranite along with one of the basalt samples are more enriched in all elements and especially LILE. In the Pearce (1996) diagram (**Figure 18**), this enrichment is interpreted as a contamination of a depleted mantle source by a subduction component. The association of serpentinites, gabbros,

plagiogranites and basalts is part of a typical ophiolite assemblage, suggestive of an oceanic crust. Therefore, this ophiolite probably represents a supra-subduction back- or fore-arc basin.

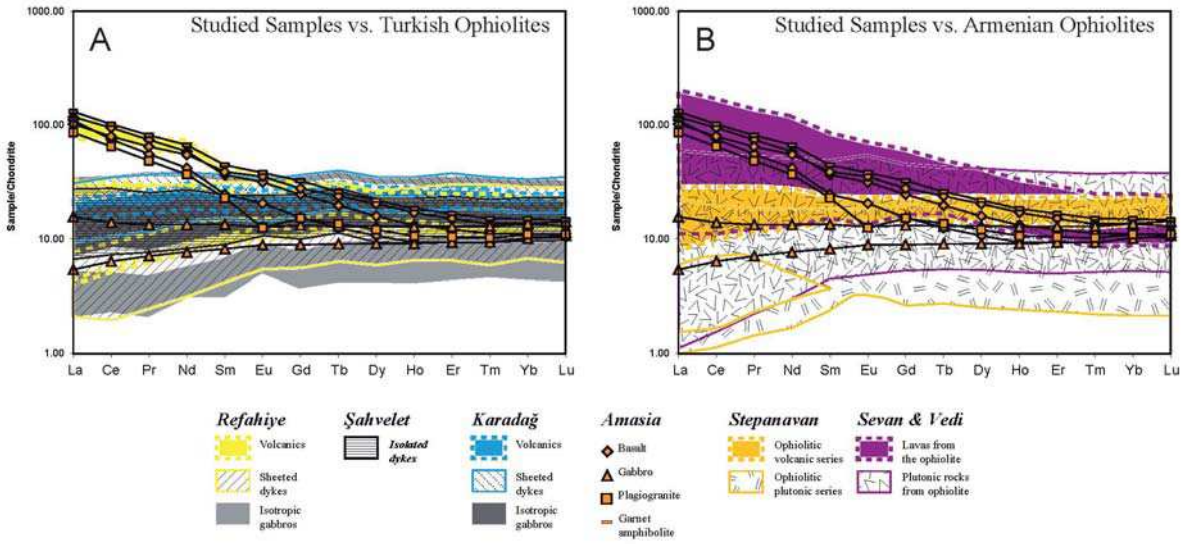

Figure 19 - Chondrite normalized REE spider diagrams. Data concerning Erzinncan-Erzurum region (Refahiye, Şahvelet and Karadağ) from Parlak et al. (2012) and concerning Stepanavan, Sevan and Vedi from Galoyan et al. (2007; 2009) and Rolland et al. (2009b; 2010). Normalizing values are from Sun and McDonough (1989).

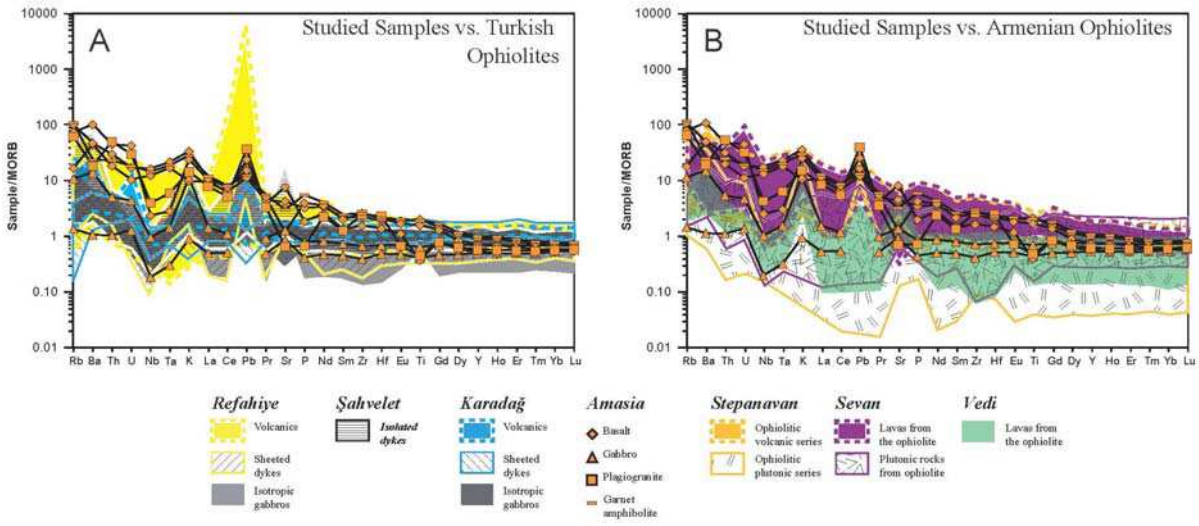

Figure 20 - N-MORB normalized multi-element spider diagrams. Data concerning Erzinncan-Erzurum region (Refahiye, Şahvelet and Karadağ) from Parlak et al. (2012) and concerning Stepanavan, Sevan and Vedi from Galoyan et al. (2007; 2009) and Rolland et al. (2009b; 2010). Normalizing values are from Sun and McDonough (1989).

1.5.3 Alkaline signature

The second tendency that is observed is formed by rocks with an alkaline basalt composition. Spidergrams show neat enrichments in LILE, LREE, Ti and Pb for these samples, with no Nb-Ta negative anomalies in respect to LREE enrichment (**Figures 19** and **20**). The garnet bearing amphibolite has a very similar composition to that of alkaline basalts either plotting in Ti/Y vs. Nb/Y and Zr/Ti vs. Nb/Y diagrams as alkaline or transitional rocks (**Figure 17**). The amphibolite also displays similar patterns as alkaline basalts in spider diagrams. The basalt MORB-normalized spider-diagrams and plot in the Pearce (1996) diagram are consistent with an Ocean Island Basalt (OIB) signature, characterized by lack of Nb and Ta negative anomalies and general enrichment in incompatible elements. Particularly, the samples show depletion in HREE which may be explained by a different source containing garnets. As quoted by Galoyan (2008), we interpret these features as representing an OIB signature.

1.6 Discussion

The similarities between the analyses obtained in Amasia with the different study areas in Armenia and NE Turkey reinforce the model proposed in several former publications, in which a single oceanic crustal domain was obducted at the scale of the Lesser Caucasus (Galoyan, 2008; Galoyan et al., 2009; Rolland et al., 2009b; 2010; 2011a-b; Sosson et al., 2010), proposed at the scale of Armenia and for NE Turkey (Parlak et al., 2012). In the following discussion we propose the first comparison of geochemical data from both sides putting some light on this large-scale ophiolite obduction, and related processes: formation of the metamorphic rocks beneath the ophiolite and post-ophiolite OIB event.

1.6.1 Comparison of Amasia ophiolite Ar-Ar ages with other ophiolites along Turkey (to the W) and Armenia (to the E) Izmir-Ankara-Erzincan-Sevan suture

The petrochemical characteristics and Ar-Ar age of the Amasia ophiolite are similar to those of the Stepanavan and Sevan ophiolites (Galoyan et al., 2007; 2009; Rolland et al., 2009b; 2010) to the East, with an overall tholeiitic tendency influenced by a subduction component. These similar results tend to infer that the ophiolites correspond to the formation

of oceanic crust in the same setting, thus suggesting the lateral continuation of these structures. $^{40}Ar/^{39}Ar$ hornblende ages obtained by Galoyan et al. (2009) in the Sevan ophiolite are of 170.5 ± 4.4 Ma and 165.3 ± 1.7 Ma, while $^{40}Ar/^{39}Ar$ dating experiments by Rolland et al. (2010) in the Vedi one provided a magmatic crystallization age of hornblende at 178.7 ± 2.6 Ma, and further evidence of greenschist facies crystallization during hydrothermal alteration until *c*. 155 Ma. Therefore, the ages obtained in the Amasia ophiolite by the same method at 169.0 ± 4.6 Ma and 175.8 ± 7.7 Ma confirm the Middle Jurassic age of the ophiolite. Based on the ages of the three locations it can be suggested that the Armenian ophiolites are part of the same obducted oceanic crust section of c. 170-175 Ma age that underwent hydrothermal alteration for about 10 Ma after oceanic crust crystallization, which is the case in slow-spreading ophiolite types (see discussions in Galoyan et al., 2009 and Rolland et al., 2009b, 2010). Similar ages of gabbro amphiboles are found in northern Turkey along the İzmir-Ankara-Erzincan suture with $^{40}Ar/^{39}Ar$ plateau ages between 167 and 177 Ma, suggesting a similar age for oceanic crust formation (Çelik et al., 2011).

1.6.2 Comparison of Amasia geochemistry with other ophiolites, Turkey (to the W) and Armenia (to the E), along Izmir-Ankara-Erzincan-Sevan suture

Considering their geochemical composition the Amasia gabbros bear similar characteristics as for other Armenian ophiolites, marked by a supra-subduction contamination with depletions in Nb-Ta, and general LILE enrichment. This evidences their emplacement in a context with a high contamination of slab-derived fluids. As a full ophiolitic lithological assemblage has been found in Armenian ophiolites (comprising radiolarites, pillow basalts, gabbros, plagiogranites and serpentinites), these rocks likely feature the formation of oceanic crust in a marginal basin environment (fore- or back-arc). The main problem for the interpretation of this marginal basin in terms of fore- or back-arc is the position of the former volcanic arc that should have been formed at this time. In Armenia, the presence of meta-volcanites in the blueschist units found below the obduction in Stepanavan (Rolland et al., 2009b) suggests that the arc was subducted and thus the basin was a back-arc one. However, the question is still posed. The most likely polarity for the former subduction zone is north dipping from the south of the marginal basin. This is suggested by the overall south verging tectonic pile, comprising the Eurasian margin, the ophiolite and the SAB (**Figure 9**).

Further, an alkaline (OIB) tendency is also observed for some of the metamorphic rocks, and basalts topping the ophiolite section. Similar OIB compositions are also found in Turkey associated to the ophiolite (Refahiye and Karadağ volcanites, Parlak et al., 2012). This alkaline composition is compatible with the presence of a series of rocks formed from a mantle plume emplaced on top of the ophiolite. Its emplacement in Armenia has been dated at c. 117 Ma by Ar-Ar on amphibole (Rolland et al., 2009b), prior to the obduction of the oceanic domain in the Coniacian-Santonian (**Table 4**).

In contrast to the tholeiitic suite, the alkaline suite shows no sign of slab derived components, and is more likely related to an enriched mantle source, such as that in hot spot settings, and is thought to be unrelated to the subduction. But some lateral influence of the subduction zone with the mantle plume is not impossible.

1.6.3 Emplacement of the ophiolite by obduction onto the South Armenian Block

This ophiolite, now linked to the others to the East (Stepanavan), already linked to the other Armenian ophiolites (Sevan and Vedi), requires at least 60 km tectonic transport from the Sevan-Akera suture to Vedi for its emplacement in its current position. The geochemical composition of the metamorphic unit beneath the ophiolite, comprised of a tectonized melange including garnet amphibolites, shows a distinct alkaline tendency similar to the alkaline suite described on top of the ophiolite in other Armenian locations (see previous section). Observations undertaken in the Amasia area are thus compatible with a model of obduction of a back-arc domain with oceanic crust slicing after OIB emplacement, which explains why we find alkaline rocks both underneath and on top of the ophiolite. The alkaline outcrops would have been under-thrusted as the ophiolite underwent an intra-oceanic scaling process.

However, considering the intra-oceanic subduction, the volcanic arc is missing. The only evidence of any remains of such a volcanic structure can be found in the ophiolitic sole by geochemical signatures. Two hypotheses on the disappearance of this arc are (1) the alteration and erosion of the volcanic arc during the obduction or (2) the subduction of the fore-arc block dragging the volcanic arc with it, as proposed by Shemenda (1994), and as suggested by some volcanic blocks in the Stepanavan blueschists. More to the west, in eastern

Turkey, remnants for such intra-oceanic subduction have been found (Parlak et al., 2012; Topuz et al., 2012).

1.6.4 Reconstruction of the 'ophiolite' history

From all the available geological data, we propose the following model for the evolution of the Amasia Ophiolite (**Figure 21**):

1- The magmatic and metamorphic rocks of the Amasia ophiolite have similar geochemical compositions to those of the other Armenian ophiolites (Sevan, Stepanavan and Vedi) as well as the Turkish ophiolites (Refahiye, Şahvelet and Karadağ). The ophiolitic rocks of Amasia are of similar age to those of the other Armenian ophiolites (around 170 Ma) (Galoyan et al., 2009; Rolland et al. 2009a; 2009b; Sosson et al., 2010).

2- The two magmatic suites were emplaced one on top of the other: a gabbroic basement of supposedly back-arc oceanic crust topped by thick basaltic flows with an alkaline tendency. This confirms the hypothesis of a single ophiolitic nappe (Galoyan, 2008) over the SAB topped by a volcanic series of hot-spot type, dated c. 117 Ma in Rolland et al. (2009b).

3- The ages of the syn-tectonic sedimentary deposits limit the beginning of obduction of this oceanic domain to Coniacian-Santonian times. Dating undergone on the flysch at Sevan and Vedi indicate similar dates. This is compatible with the context of the closing of Neotethys.

4- This new contribution in the comprehension of the geodynamic evolution of the Lesser Caucasus supports the presence of two north dipping subductions zones: (1) a subduction under the Eurasian margin and to the south by (2) an intra-oceanic subduction allowing the continental domain to subduct under the oceanic lithosphere, thus leading to ophiolite emplacement. This confirms recent geodynamic models (Rolland et al., 2010; Sosson et al., 2010).

5- The missing of the volcanic arc formed above the intra-plate subduction may be explained by its dragging under the obducting ophiolite with scaling by faulting and tectonic erosion. It is hypothesized that the generation of blueschists of Stepanavan corresponds to this missing volcanic arc (Galoyan et al., 2007; Rolland et al., 2009a). In the Erzincan region geochemical traces (Parlak et al., 2012) and field observations lead to the confirmation of this hypothesis because of low-grade metamorphic rocks of

volcanic origin that may be found under ophiolitic rocks overthrusted from north to south along the northern edge of the Erzincan basin.

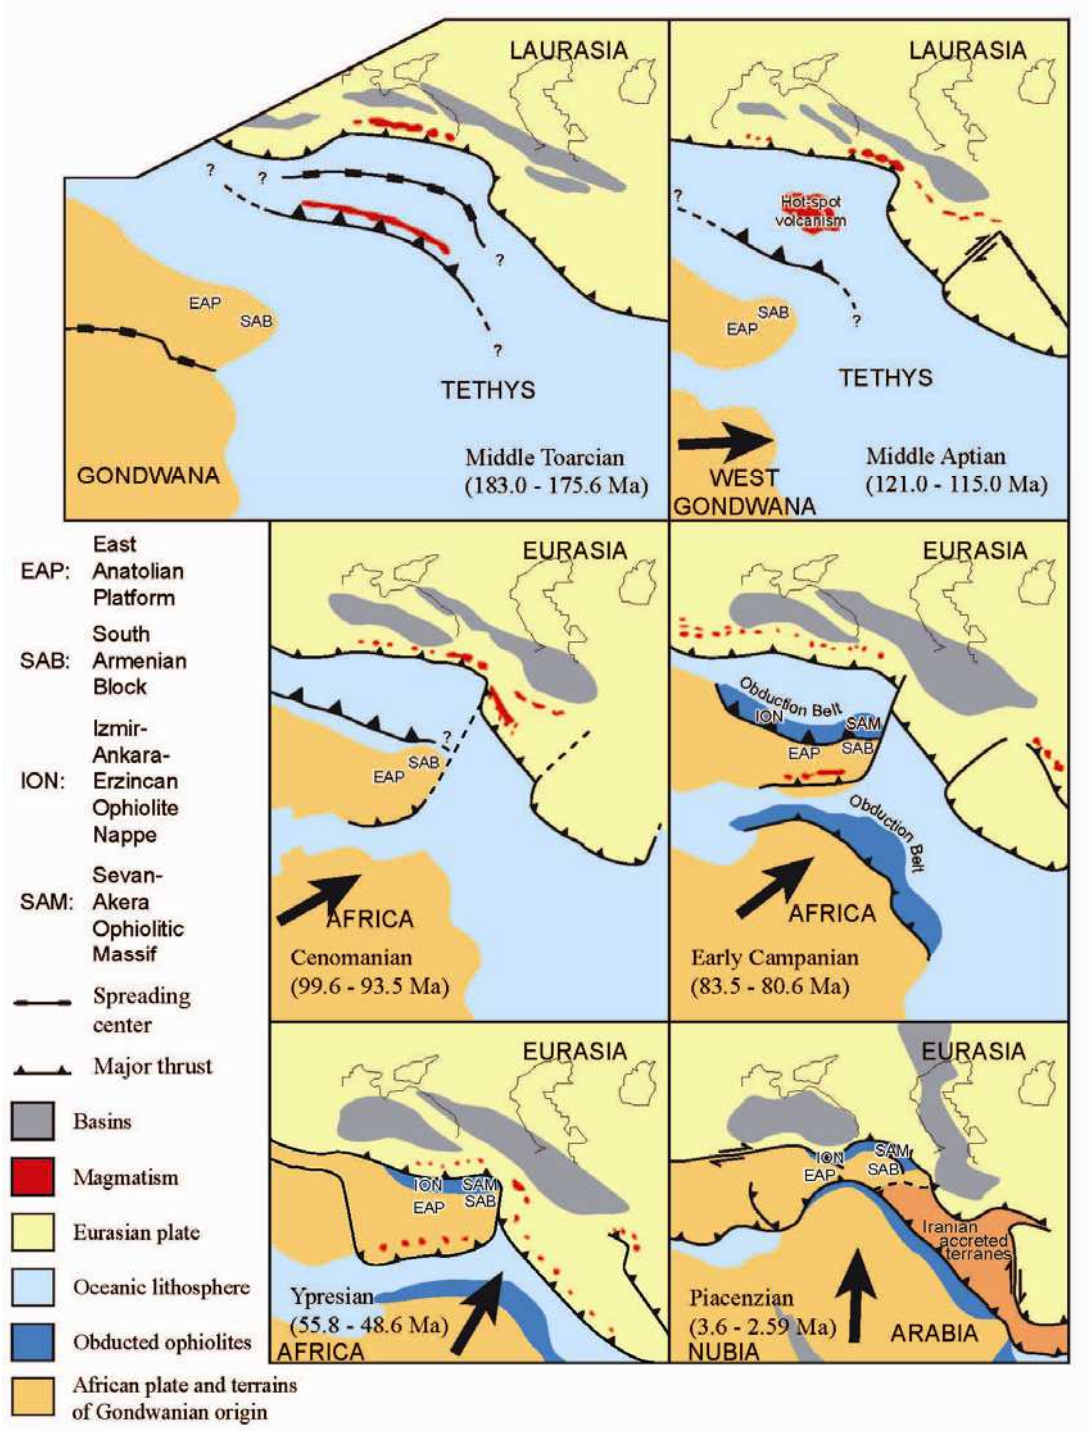

Figure 21 - Middle Toarcian (c. 180 Ma), to Early Campanian (c. 83 Ma) palaeotectonic evolution of the Lesser Caucasus region and its neighboring areas, modified from Middle East Basins Evolution Programme palaeotectonic maps of the Middle East (Barrier and Vrielynck, 2008) to include our new data.

1.6.5 Conclusive remarks and perspective of work

The petro-geochemical features and age of the Amasia ophiolite are in part similar to those of the Armenian ophiolites to the east (Galoyan, 2008) and the Turkish ophiolites to the west (Parlak et al., 2012), particularly the Jurassic part of the ophiolite, which may have been formed in a similar context. In the Jurassic times, the same processes might be responsible for the formation of the Amasia ophiolite and the other Armenian and Turkish ophiolites, including a back-arc setting environment. Several hypotheses might be drawn at this stage of the study. (1) The Armenian ophiolites might represent the continuation of the Turkish ophiolites along the Ankara-Erzincan suture zone further east. This hypothesis is supported by the fact that the Armenian ophiolite nappe is shown to be transported on a metamorphic sole, and is shown to be obducted onto the SAB (Knipper and Khain, 1980). We propose that this obduction connects to the basal contact of the NE Turkish ophiolite, but still few ages were obtained on the ophiolites there to validate this hypothesis. However, lateral continuation from Armenia to NE Turkey is apparent from the geometry and position of ophiolites on geological maps. Such correlation suggests an obducted ophiolitic nappe of at least 700 km in length along the Ankara-Erzurum-Sevan-Akera suture zone on top of the Tauride block continuing laterally to the SAB. In view of the information brought to light within this paper, the Izmir-Ankara-Erzincan-Sevan-Akera ophiolite obduction is amongst the most exceptional case of obduction on earth.

As for the correspondence with the peri-Arabic ophiolites (for example the Oman ophiolite), the oceanic domains were obducted onto Arabia within the same time span as those obducted onto the SAB and Tauride block (Okay et al., 2001; Agard et al., 2010; Sosson et al., 2010). However, preliminary paleomagnetic analyses to determine the movements of the continental fragments indicate that the SAB and the Tauride block were much closer to the Eurasian margin than the Arabian margin (Meijers et al., 2012). From this work it also would seem that an ocean domain separates the SAB and Tauride block from the Arabian margin until Upper Cretaceous times. This ocean domain corresponding to southern Neotethys closes completely during Eocene times (Rolland et al., 2012).

The preservation of initial obduction contacts and ophiolite structure makes it a potential target for understanding the obduction processes leading to such important tectonic transport of oceanic crust remnants onto continental lithospheres.

II.2 Article 2 – P-T-t history of the Amasia ophiolite "metamorphic sole" (Amasia, Lesser Caucasus): implications for the obduction process of an old oceanic lithosphère

Notre cartographie du massif ophiolitique d'Amasia a mis en évidence (1) de la croûte océanique gabbroïque non métamorphisée, (2) des serpentinites ainsi qu'un mélange tectonique de faciès schiste vert et (3) une tranche basale d'amphibolites à grenat incorporée dans ce mélange. Le contact d'obduction initial étant préservé en fait une cible potentielle pour la compréhension des processus correspondant à la propagation d'une nappe ophiolitique en obduction, en particulier concernant les étapes de transport tectonique d'un segment de croûte océanique sur une lithosphère continentale. D'après Meliksetyan *et al.* (1984), les amphibolites à grenat d'Amasia témoignent d'un métamorphisme polyphasé. Ces amphibolites donnent un âge Carbonifère moyen (330 Ma) par la méthode Rb-Sr pour le faciès éclogite, et Santonien-Campanien (80 ± 5 Ma), par la méthode K/Ar attribué au faciès schiste vert par ces auteurs. Cependant, il semble totalement improbable que les amphibolites à grenat se soient formés il y a 330 Ma puisque l'âge de la croûte océanique dont semblent elles dériver est Jurassique ! De plus, l'application de méthodes géochronologiques telles que Rb-Sr et K/Ar sur roche totale sur ces lithologies ayant fortement subi de l'hydrothermalisme, n'est pas appropriée. Nous verrons cependant que le dernier âge de 80 Ma se rapproche fortement de celui que nous avons obtenu par la méthode Ar-Ar.

Dans la section précédente nous avons pu asseoir le fait que toutes les ophiolites arméniennes font partie du même ensemble. 50 km à l'est d'Amasia, le massif ophiolitique de Stepanavan présente aussi des roches métamorphiques, en position basale de l'unité ophiolitique, mais de faciès schiste bleu, localement réchauffé dans le faciès amphibolites (amphibolites à glaucophane-zoïsite avec ou sans grenat) (Galoyan *et al.*, 2007; Rolland *et al.*, 2009a). Les travaux de Morkovkina *et al.* (1982) ont montré en utilisant la méthode K/Ar que ces amphibolites à grenat ont un âge de 164 ± 16 Ma et les amphibolites à glaucophane ont un âge de 90 ± 10 Ma (sur glaucophane). Ce deuxième âge confirme les âges obtenus avec la même méthode sur les mêmes amphibolites à glaucophane de 83-85 Ma (sur glaucophane) par Baghdasaryan *&* Ghukasyan (1962). Par ailleurs, le glaucophane ne contenant pas de K, il semblerait plutôt que ces auteurs aient pu dater des inclusions de mica blanc. Plus récemment

Rolland *et al.* (2009a), en utilisant la méthode $^{40}Ar/^{39}Ar$ sur phengites, ont montré que les amphibolites à glaucophane de Stepanavan ont subi un métamorphisme polyphasé. L'âge de 95-91 Ma obtenu sur les phengites de haute pression est interprété comme marqueur d'un métamorphisme HP au cours d'une phase de subduction au Cénomanien-Turonien. L'âge de 73,5-71 Ma donné par des phengites associées à un cisaillement de plus basse pression indique que cette première phase de subduction est suivie d'une phase de déformation au cours de l'exhumation dans le faciès schiste vert (épidote-amphibolite) pendant le Campanien supérieur-Maastrichtien. Les auteurs proposent que ceci marque l'entrée dans la subduction sous l'Eurasie du SAB.

En vue de ces nouveaux résultats et interprétations, utilisant la méthode $^{40}Ar/^{39}Ar$ moins sujette à des perturbations dus à des processus géologiques postérieurs, nous avons entrepris une nouvelle étude petro-chronologique des amphibolites à grenat du massif d'ophiolitique d'Amasia. Les roches métamorphiques montrent deux paragenèses : (1) un assemblage grenat-amphibole, entouré par (2) un deuxième assemblage chlorite-phengite. La thermobarométrie révèle un chemin de sens antihoraire défini par (1) un pic HT-LP de $6 < P < 7$ kbar , $T > 630$ ° C et (2) un pic MT-MP à $8 < P < 10$ kbar , $580 < T < 620$ ° C. Nous proposons que cette semelle métamorphique a été amphibolitisée le long d'un gradient très élevé pour ensuite être incorporée dans un mélange de MP-MT. L'incorporation d'écailles de petite dimension dans ce mélange conduit à son refroidissement au cours d'un enfouissement/épaississement, et peut-être à une augmentation légère des conditions de pression.

Les nouvelles datations $^{40}Ar/^{39}Ar$ ont été réalisées sur les amphiboles (hornblende) et micas blanc (phengite) afin de contraindre temporellement les conditions pic des paragenèses HT et MP. Les âges obtenus sont similaires, dans les marges d'erreurs, donnant 90,8 ± 3,0 Ma et 90,8 ± 1,2 Ma pour les amphiboles et les phengites, respectivement. Nous interprétons ces nouvelles données comme un témoin d'une évolution tectonique très rapide. Nous avançons alors un scénario intégrant (1) l'écaillage d'une partie de la croûte océanique et son sous-charriage à l'avant de l'obduction à c. 91 Ma, la croûte océanique chevauchante étant relativement chaude. Ensuite, le système évoluerait jusqu'à (2) l'incorporation de ces écailles dans la partie basale de l'obduction (la semelle) à c. 90-88 Ma.

Ce modèle est soutenu par la subsistance d'un gradient géothermique relativement chaud suite à la mise en place d'OIB à 117 Ma (à Stepanavan; Rolland *et al.*, 2009b) ainsi que

des datations biostratigraphiques (radiolaires; Danelian *et al.*, 2014) témoignant de la mise en place de laves sur la future ophiolite au Cénomanien.

Remarquons que les deux chemins PTt, proposés par Rolland *et al.* (2009a) pour les roches métamorphiques de Stepanavan et celui que nous proposons pour celles d'Amasia, convergent dans des conditions MP-MT (5,5 kbar, 500 ° C). Cela suggère leur couplage dans le prisme d'accrétion de la subduction sous l'Eurasie et donc une exhumation commune au cours de l'Eocène.

Cette étude a fait l'objet d'une publication en qui sera prochainement soumise dans *Journal of the Geological Society*.

P-T-t history of the Amasia ophiolite 'metamorphic sole' (Armenia, Lesser Caucasus): implications for the obduction process of an old oceanic lithosphere

M. Hässig[1,*], Y. Rolland[1], M. Sosson[1], G. Galoyan[2], A. Avagyan[2]

Abstract

The Sevan-Akera suture zone ophiolites form part of a major obduction, up to 300 km of horizontal transport, of the northern branch of Neotethys oceanic crust over the South Armenian/Taurides continental block. The emplacement of these ophiolites occurred throughout Coniacian to Santonian times (91-83 Ma), prior to continent-continent collision. Near the locality of Amasia (NW Armenia), garnet-bearing amphibolites are embedded within a greenschist facies tectonic mélange unit found below the base of the non-metamorphic obducted oceanic unit. The metamorphic rocks show two parageneses: (1) a HT-LP assemblage of garnet-amphibole, surrounded by (2) MP-MT retrogression by chlorite-phengite. Thermobarometry reveals a counterclockwise path defined by (1) a HT-LP peak of $6 < P < 7$ kbar, $T > 630$°C and (2) a MT-MP peak at $8 < P < 10$ kbar, $580 < T < 620$°C. $^{40}Ar/^{39}Ar$ dating on amphiboles (hornblende) and white micas (phengite) yields for both HT and MP peaks similar within-error ages of 90.8 ± 3.0 Ma and 90.8 ± 1.2 Ma, respectively. The PTt history of the metamorphic sole argues for a rapid tectonic process, including the slicing of oceanic crust and its incorporation within an accretionary prism below a relatively hot oceanic crust at c. 91-90 Ma. This metamorphic sole was first amphibolitized along a HT-MP gradient, due to a relatively hot geotherm following the emplacement of OIB at 117 Ma. Secondly, the thickening of the overriding compartment of this subduction zone at c. 90-88 Ma caused these conditions to change to MT-MP, as the South Armenian Block entered the subduction zone. Blueschist facies rocks at Stepanavan (N Armenia) occur in a similar tectonic position along the Sevan-Akera suture farther East. The blueschists show a slightly older HP-LT peak (95-91 Ma) followed by a younger (73-71 Ma) MT-MP peak as compared to the Amasia amphibolites. Both PTt paths converge at MP-MT conditions (5.5 kbar, 500°C) suggesting their coupling in the accretionary prism, and thus inferring common exhumation in the Eocene. The obduction process ended within 1-5 Ma of its onset, at 89-83 Ma, as indicated by paleontological ages in both under-thrusted (sub-ophiolitic) and uncomformably overlying (supra-ophiolitic) sediments.

Key Words: obduction, ophiolite, metamorphic sole, counter-clockwise PT path, Lesser Caucasus

2.1 Introduction

There is still much controversy concerning the explanation of oceanic crust obduction initiation and subsequent transport onto the continental crust. Obducted ophiolite sequences generally include thick slices of undeformed oceanic lithosphere originating from a supra-subduction zone setting, detached from its mantle basement and obducted over a continental margin (Spray, 1983). Models for obduction initiation include an early stage of buckling (Agard *et al*., 2007) or ridge subduction (Hacker, 1991), leading to intra-oceanic thrusting, which may result in the development of a metamorphic sole (e.g., Michard *et al*., 1991). Later, the intra-oceanic subduction process continues to a 'marginal' stage where the oceanic lithosphere is thrusted over the passive continental margin (Dilek and Whitney, 1997; Gray and Gregory, 2000; Engi *et al*., 2001; Bortolotti *et al*., 2005), or under-plated by the latter, known as obduction. The relative position of the initiation of intra-oceanic thrusting, the particular physical and/or geochemical properties of the lithologies forming the involved oceanic lithospheres (e.g., the role played by plume events) and geodynamic settings recorded throughout the metamorphic processes are still subject to debate (e.g., Agard *et al*., 2007).

The reconstruction of the geodynamic evolution of oceanic basins that were formed in the Neo-Tethyan domain allows better identification and understanding of the role of the dominant factors involved in oceanic closure, including obduction processes. Key examples of obducted ophiolite sequences are found throughout the Tethyan collisional belts (Adamia *et al*., 1981; Göncüoğlu and Turhan, 1984; Hempton, 1985; Zakariadze *et al*., 1990; Yılmaz, 1993; Lytwyn and Casey, 1995; Carosi *et al*., 1996; Hacker *et al*., 1996; Searle and Cox, 1999; Okay *et al*., 2001; Ding *et al*., 2005; Barrier and Vrielynck, 2008; Galoyan, 2008; Gaggero *et al*., 2009; Agard *et al*., 2010; Oberhänsli *et al*., 2010; Parlak *et al*., 2012; Rolland *et al*., 2012). Part of the history of central and northern Neotethys can be deduced from both the study of the oceanic crust obducted in the Armenian Lesser Caucasus and of the metamorphic rocks found directly underneath the ophiolite bodies, whose formation is linked to ophiolite emplacement (e.g., Sengör and Yılmaz, 1981; Ricou *et al*., 1985; Dercourt *et al*., 1986; Ricou, 1994; Harper *et al*., 1996; Dilek and Whitney, 1997; Okay and Tüysüz, 1999; Zakariadze *et al*., 2005; Elitok and Drüppel, 2008; Festa *et al*., 2010). Such 'suture zone' lithologies provide key timing and palaeogeographic data for geodynamic reconstructions of the still puzzling region stretching from the Mediterranean area to SE Asia (Stampfli and Borel, 2002; Robertson, 2004; Barrier and Vrielynck, 2008; Galoyan *et al*., 2009; Rolland *et al*., 2010; Sosson *et al*., 2010). Furthermore, their geometry and geochemistry provide key

information in order to reconstruct the nature of the oceanic domain which has now disappeared (Cloos and Shreve, 1988; Ellis *et al*., 1999; Engi *et al*., 2001; Stampfli *et al*., 2001; Federico *et al*., 2007; Galoyan, 2008; Gaggero *et al*., 2009; Guilmette *et al*., 2009; Rolland *et al*., 2009a) and thus the setting prior to metamorphism of subducted rocks. The Armenian part of the Lesser Caucasus region features intact and unmetamorphosed sections of obducted oceanic crust. These unique and remarkable objects were only slightly affected by the later collisional history, featuring both its metamorphic sole and its sedimentary front (Sosson *et al*., 2010; Rolland *et al*., 2012; Hässig *et al*., 2013), which enables to further reconstruct part of the obducted ophiolite nappe geometry and history.

In this paper we report new structural, petrologic, geochemical and $^{40}Ar/^{39}Ar$ chronological data obtained on the garnet amphibolite outcrop from the basal tectonic contact of the Amasia ophiolite (NW Armenia). The results obtained concerning these metamorphic rocks are coherent with a counterclockwise Pressure-Temperature-time (P-T-t) path for this unit. This path complements previous P-T-t estimates of the metamorphic rocks outcropping above the South Armenian Block (SAB) and below the obducted ophiolites in the area of Stepanavan (Rolland *et al*., 2009a). Based on the metamorphic data we propose a geodynamic reconstruction for the obduction of the Lesser Caucasus ophiolites in Armenia.

2.2 Geological setting

The study of Armenian ophiolites and associated lithologies allows the reconstruction of the northern part of the Neotethyan domain and thus identifies the processes undergone throughout the formation of this region, which the first step is progressive terrane accretion (Pourteau *et al*., 2013).

Previous works on these ophiolites along the Sevan-Akera Suture Zone in the 1970's and 1980's show a Jurassic age and multiple geochemical tendencies, interpreted as formed in a supra-subduction domain (e.g., Palandjyan, 1971; Knipper, 1975; Sokolov, 1977; Knipper and Sokolov, 1977; Knipper and Khain, 1980; Abovyan, 1981; Adamia *et al*., 1981; Zakariadze *et al*., 1983; Knipper *et al*., 1986). More recently, several authors propose models including include Neotethyan oceanic crust obduction in the Coniacian times and collision–accretion of microplates to the Eurasian margin in the Upper Cretaceous-Paleogene, before the final Arabia–Eurasia collision (Yilmaz *et al*., 1993; Knipper *et al*., 1997; Okay *et al*., 2001; Galoyan *et al*., 2007; 2009; Rice *et al*., 2009; Rolland *et al*., 2009a; 2009b; 2011; 2012; Agard *et al*., 2010; Sosson *et al*., 2010; Pourteau *et al*., 2013).

North of the Sevan-Akera Suture zone, in the Georgian part of the Lesser Caucasus, a thick magmatic arc formed above north-dipping subduction is dated to the Upper Jurassic Lower Cretaceous times (e.g. Adamia *et al*., 1981 for a review).

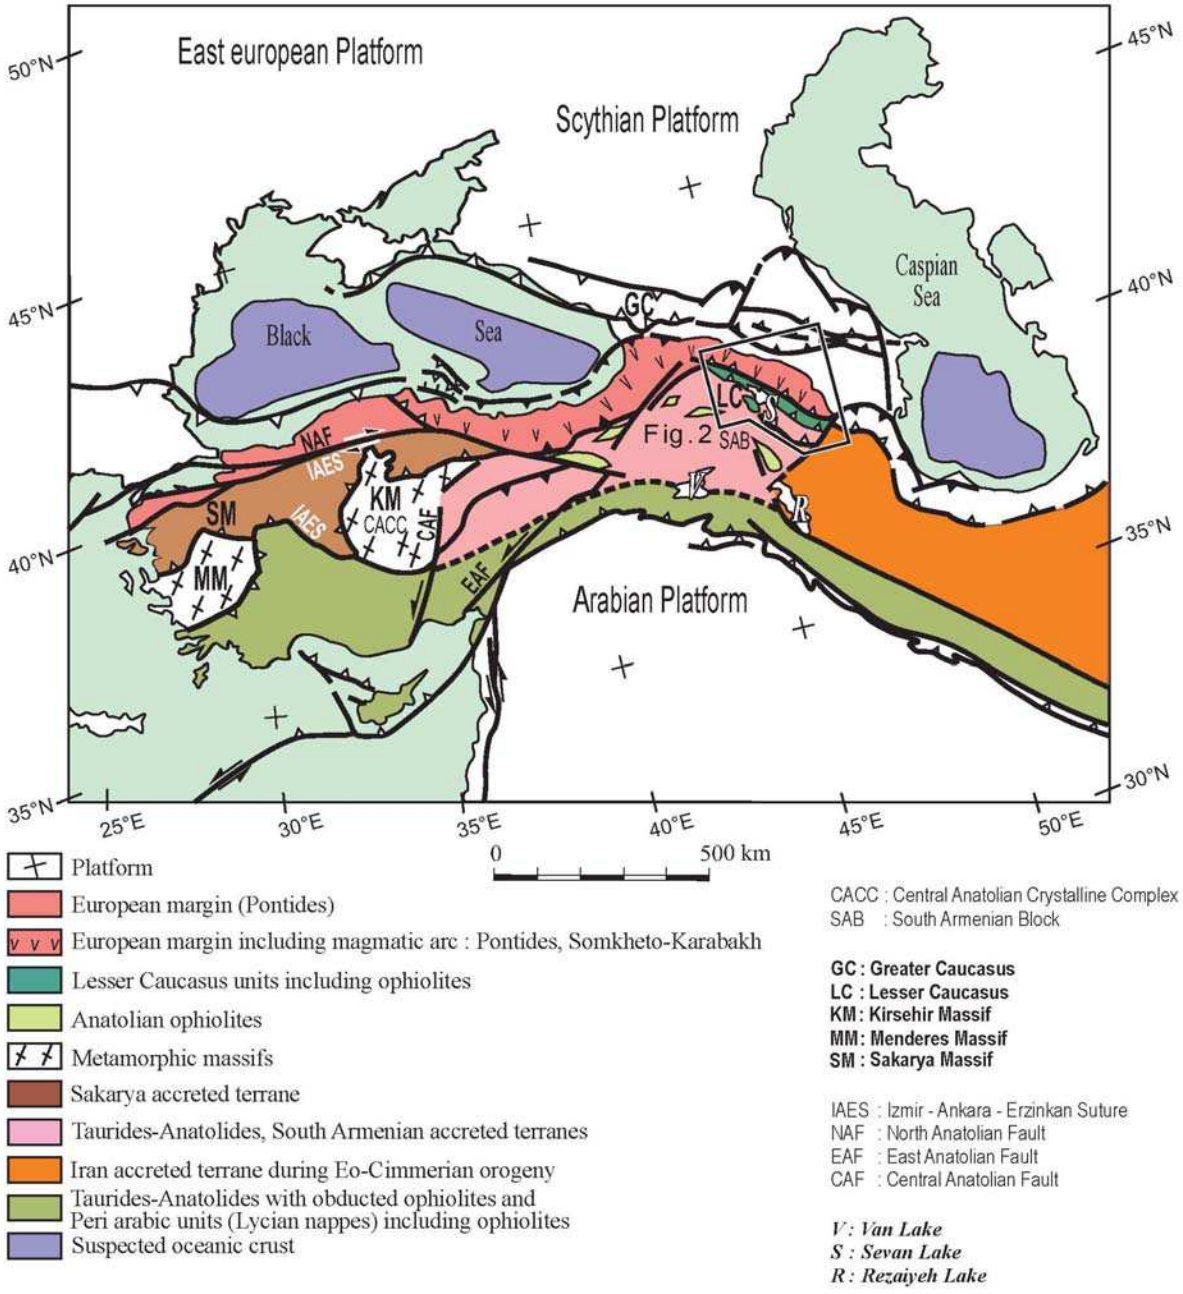

Figure 22 - Tectonic map of the Middle East–Caucasus area, with main blocks and suture zones, after Avagyan *et al.* (2005), modified. Location of Figure 23 indicated.

South of the obducted ophuiolite, the South Armenian Block (SAB) (Knipper, 1975; Knipper and Khain, 1980) is a Gondwanian originating microplate corresponding to the Taurides-Anatolides (Sengör and Yılmaz, 1981; **Figure 22**). Coniacian to Santonian (90-83 Ma) obduction onto the SAB is marked by flysch series reworking the ophiolites at the

obduction front and reef series of identical age sealing the obduction nappe in the southern part of the SAB (Vedi area: Sokolov, 1977; Sosson *et al*., 2010; **Figures 23** & **24**). These geological observations imply that two subduction zones were active at the same time: North of the SAB and south of the Georgia Eurasian margin (Rolland *et al*., 2011). Collision of the SAB with the Eurasian margin is dated as Late Cretaceous-Paleocene (Rolland *et al*., 2012). This collision/accretion results in a subduction jump to the south of the Taurides-Anatolides. This process occurred around 10 Ma after the obduction (Late Coniacian–Santonian, 88–83 Ma). In the Bitlis-Pütürge massifs of SE Turkey High Pressure (HP) metamorphic evolution is bracketed between 82-79 Ma in the Bitlis and 74-71 Ma in the Pütürge massif (Hempton, 1985; Oberhänsli *et al*., 2010; 2014; Rolland *et al*., 2012).

For a synthesis concerning the Lesser Caucasus ophiolites, we refer toGaloyan *et al*. (2007, 2009), Rolland *et al*. (2009b, 2010) and Hässig *et al*. (2013). These works evidence the following relations within the ophiolite nappe structure: (1) serpentinites cross-cut by gabbros dated at c. 175-165 Ma and overlain by basalts and radiolarites of similar age (Danelian *et al*., 2010). These rocks have tholeiitic compositions contaminated by subduction components. (2) Above these series, alkaline Ocean Island Basalt (OIB) pillow lavas emplaced in the Lower Cretaceous times.

The Amasia ophiolite is part of the ophiolite belt in northern Armenia (**Figure 23**). In Stepanavan, East of Amasia, ophiolites have been described in association with blueschist and amphibolite facies metamorphic rocks dated at 94-91 Ma, High Pressure (HP) peak, to 73-71 Ma, High Temperature (HT) retrogression (Rolland *et al*., 2009a). These metamorphic rocks evidence the presence of a subduction zone active in the Middle Cretaceous and stopping in the Late Cretaceous at 80-75 Ma (Rolland *et al*., 2011).

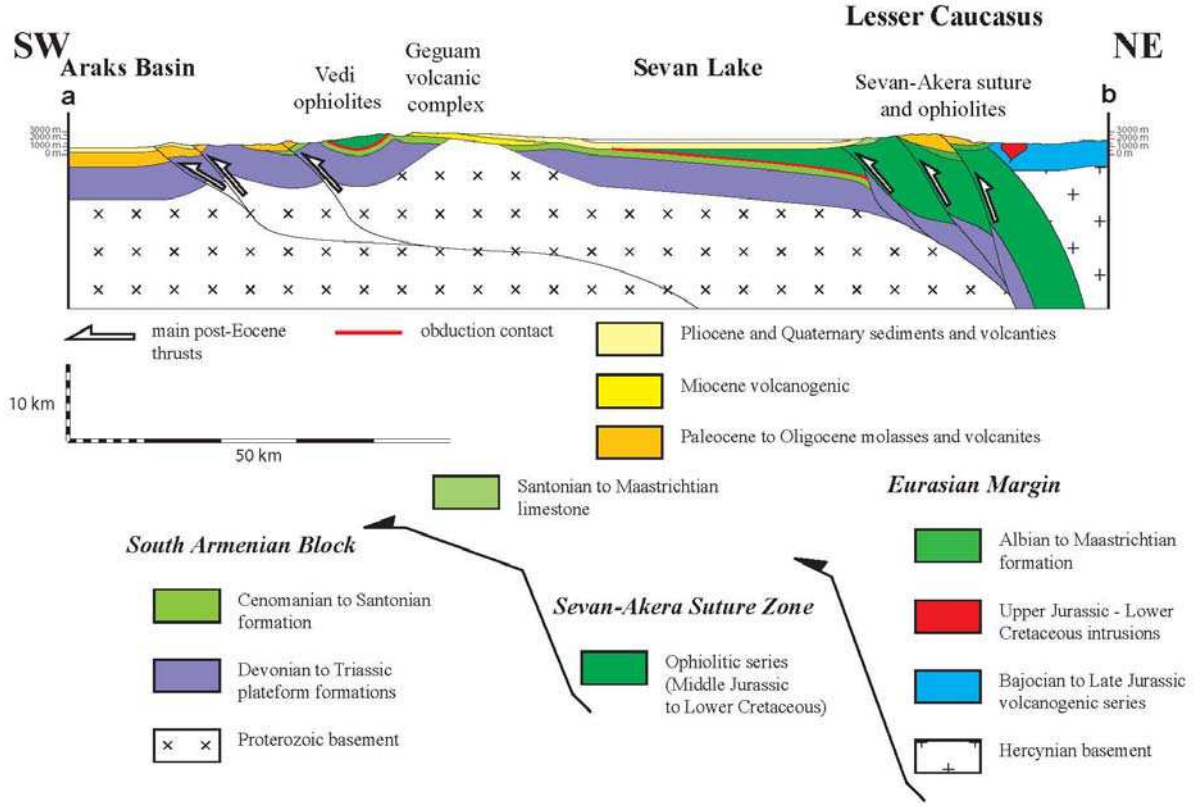

Figure 24 - Interpretative crustal-scale sketch cross-section of the Armenia-Azerbaijan transect. Location is indicated on Figure 23.

2.3 Field Observations

A full description of the geology of the Amasia ophiolite is provided in Hässig *et al*. (2013), which is summarized below. According to the field observations, the geological map and cross-sections (**Figures 25**, **26A** & **26B**), three main lithotectonic units have been identified (from top to bottom):

1 - An upper ophiolitic unit constituted by serpentinites, gabbros, basaltic pillow lavas and volcanic rocks with interlayered reef limestones. This unit, as in other localities in Armenia, is interpreted as representing un-metamorphosed obducted oceanic crust formed during mid-Jurassic times (dated at 169.0±4.6 to 175.8±3.9 Ma by $^{40}Ar/^{39}Ar$ on gabbro amphibole; Hässig *et al*., 2013). Ending of obduction is constrained by a Coniacian-Santonian (88-83 Ma) detrital deposit reworks elements from the entire ophiolite, deposited on top of this unit.

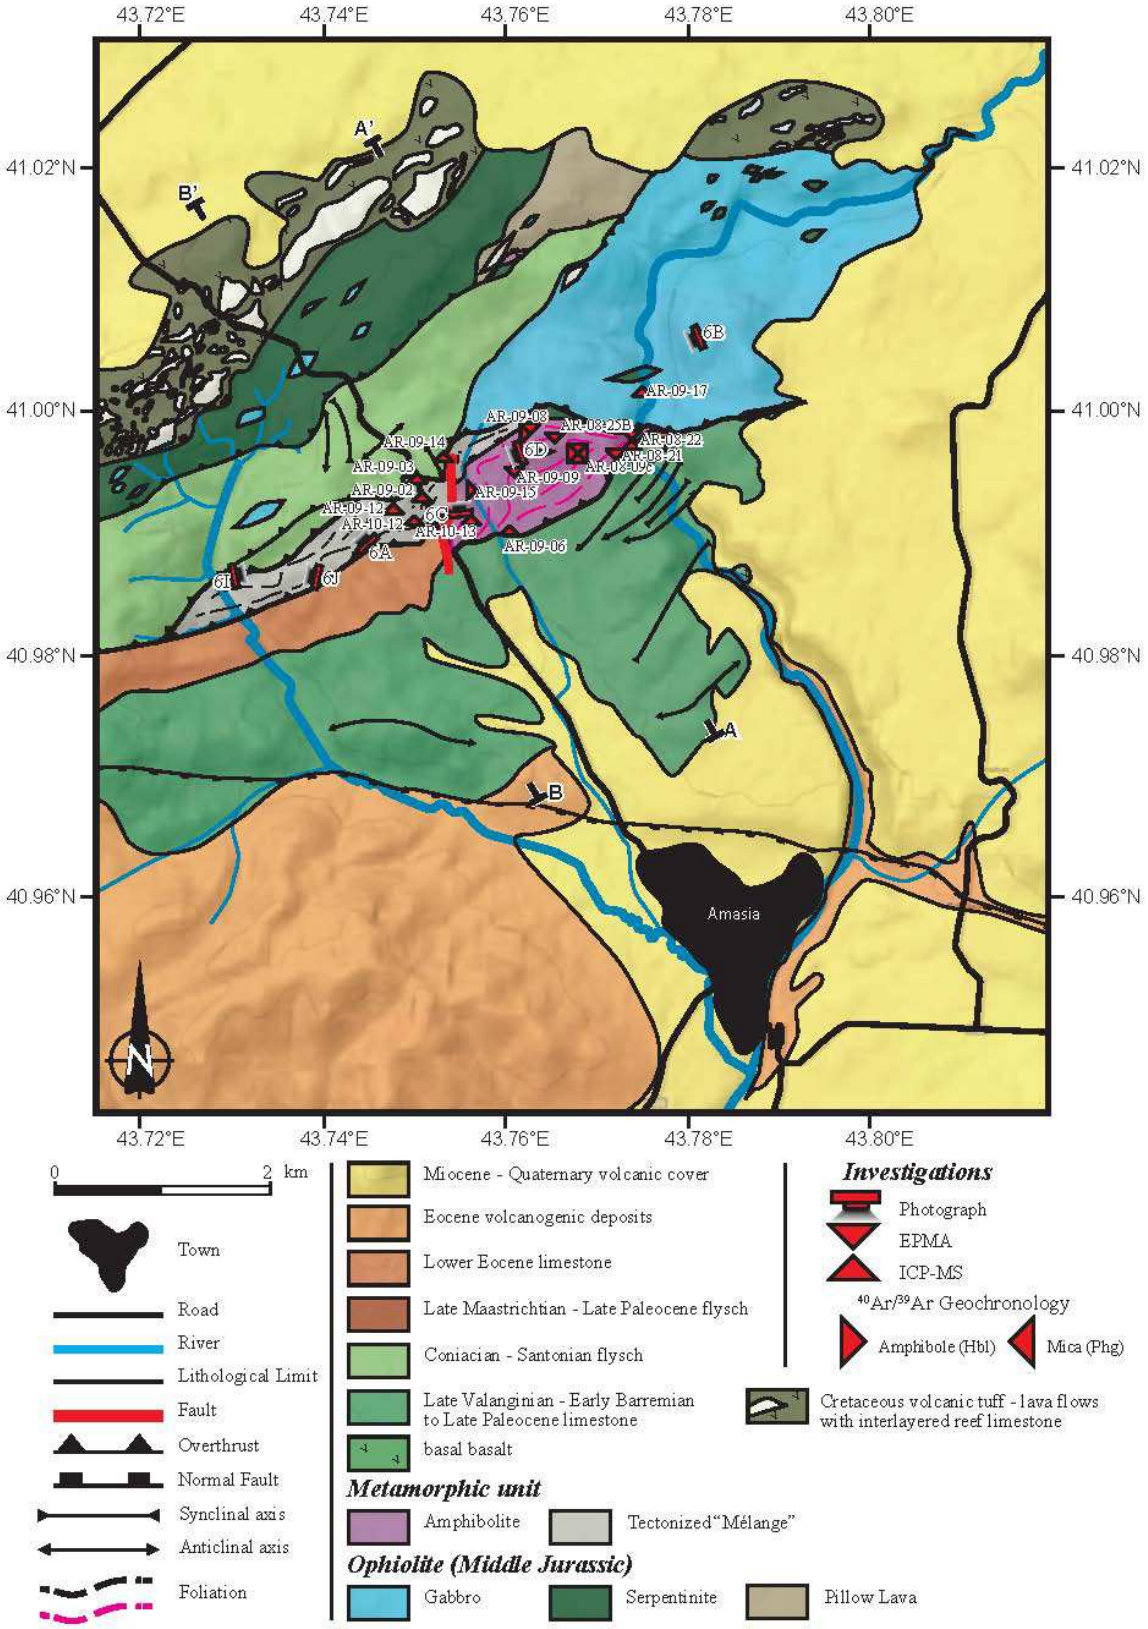

Figure 25 - Structural map of the Amasia ophiolite window. Location is indicated on Figure 23. Plot of geological sections of Figure 26B along with the locations of photographs of Figure 27 as well as of samples investigated through ICP-MS, EPMA, and $^{40}Ar/^{39}Ar$ geochronology methods of Figures 29, 30 & 32, respectively.

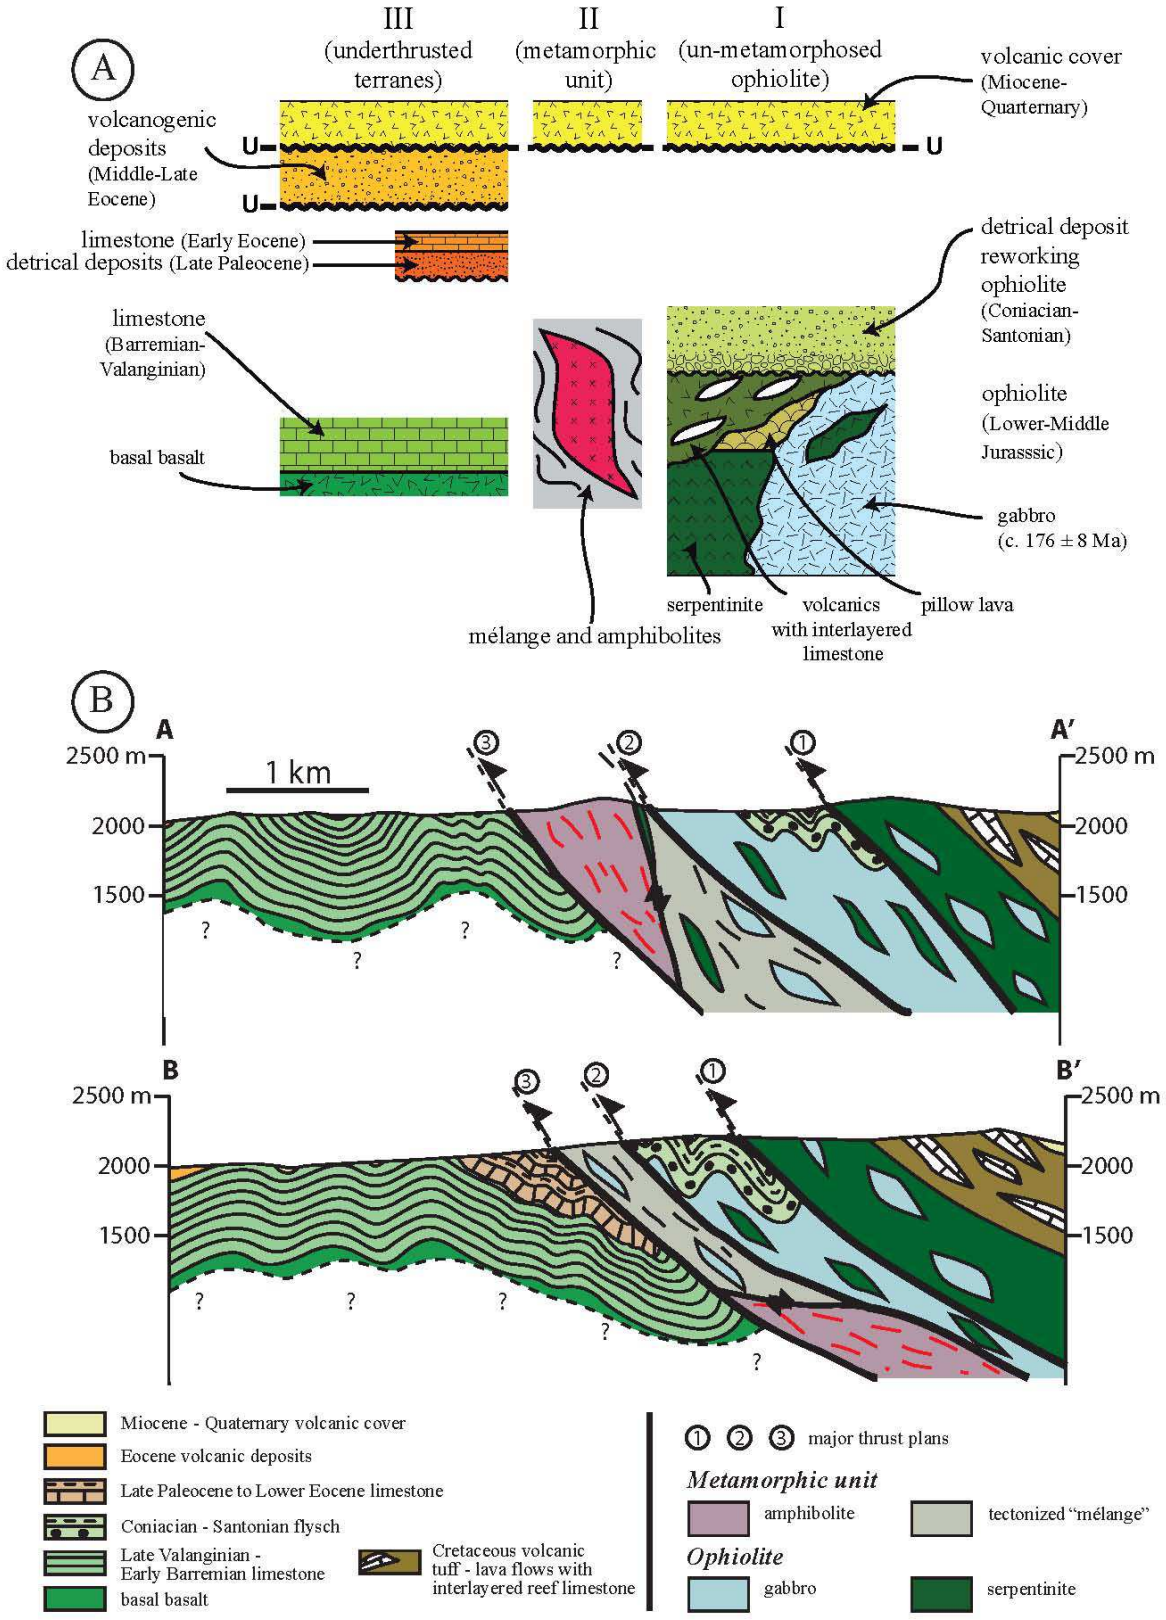

Figure 26 - (A), synthetic litho-stratigraphic record of the three main units of the Amasia ophiolite window; I) upper unit corresponding to the un-metamorphosed ophiolite, II) metamorphic unit comprising of the tectonic mélange and the lens of garnet bearing amphibolites, III) the lower (Southern) unit. (B), sketch geological cross sections of Amasia ophiolite. Locations are indicated on Fig. 25.

2 - Thrusted by the ophiolitic unit, a tectonic mélange of low grade (greenschist facies) meta-basalts, meta-cherts and metamorphosed serpentinites (**Figures 27A**, **E** & **F**) is exposed, which includes lenses of ophiolites and metasediments (**Figures 26B** & **27B**). The limestone blocks incorporated in this mélange are marbleized and arranged in elongated boudins along with serpentinites and basalts (**Figure 27A**). Kinematics indicate top-to-the-south sense of shear. Within this tectonic mélange a kilometric-size (≈ 2 km²) boudin of garnet bearing amphibolites has been mapped (**Figure 27B**). The garnet-bearing amphibolite body also has an elongated shape in the ENE-WSW direction. Amphibolites show a penetrative foliation marked by alternations of amphibole and garnet-rich dark levels alternating plagioclase and quartz-rich lighter colored levels (**Figures 27C** & **27D**). The lineation of the chlorites and phengites along with that of amphiboles and the presence of rolled garnets evidences that this unit was tectonized, with a southward sense of shear (**Figure 28**).

3 - These two units are thrusted on top of a southern (third) unit comprising brecciated basalts overlain by Lower Cretaceous limestones, unconformably covered by late Paleocene flysch grading up into Lower Eocene limestone and Mid- to Upper Eocene volcanogenic deposit. This structure features timing for final collision of SAB and Eurasia as in all of the Lesser Caucasus (see Sosson *et al*., 2010). Ongoing post-collisional magmatism is represented by a Miocene to Quaternary volcanic cover sealing the nappe-stack.

Figure 27 - (A), landscape photography of greenschist facies tectonized mélange zone featuring marbleized limestone blocks. The W-E extension and scattering of the limestone is in accordance with North to South convergence and thrusting. (B), garnet-bearing amphibolite body thrusted to the south above Cretaceous limestone. The gabbro is also thrusted to the south onto the amphibolite body in lateral continuation of a tectonized mélange. (C), field photography of garnet amphibolites. The foliation and lineation are underlined by the red plan and black double arrow, respectively. (D), photography and sketch of garnet amphibolite outcrop. The garnets (red) are preferentially located in the levels rich in white minerals (light grey), and underline the foliation as well as mineral lineation. The yellow represents moss and lichen. (E) and (F), representative field photographies and sketches of greenschist facies rocks. Intense deformation is featured by C-S structures, scaling and molding of brecciated mélange elements. Locations of viewpoints are indicated on Fig. 25.

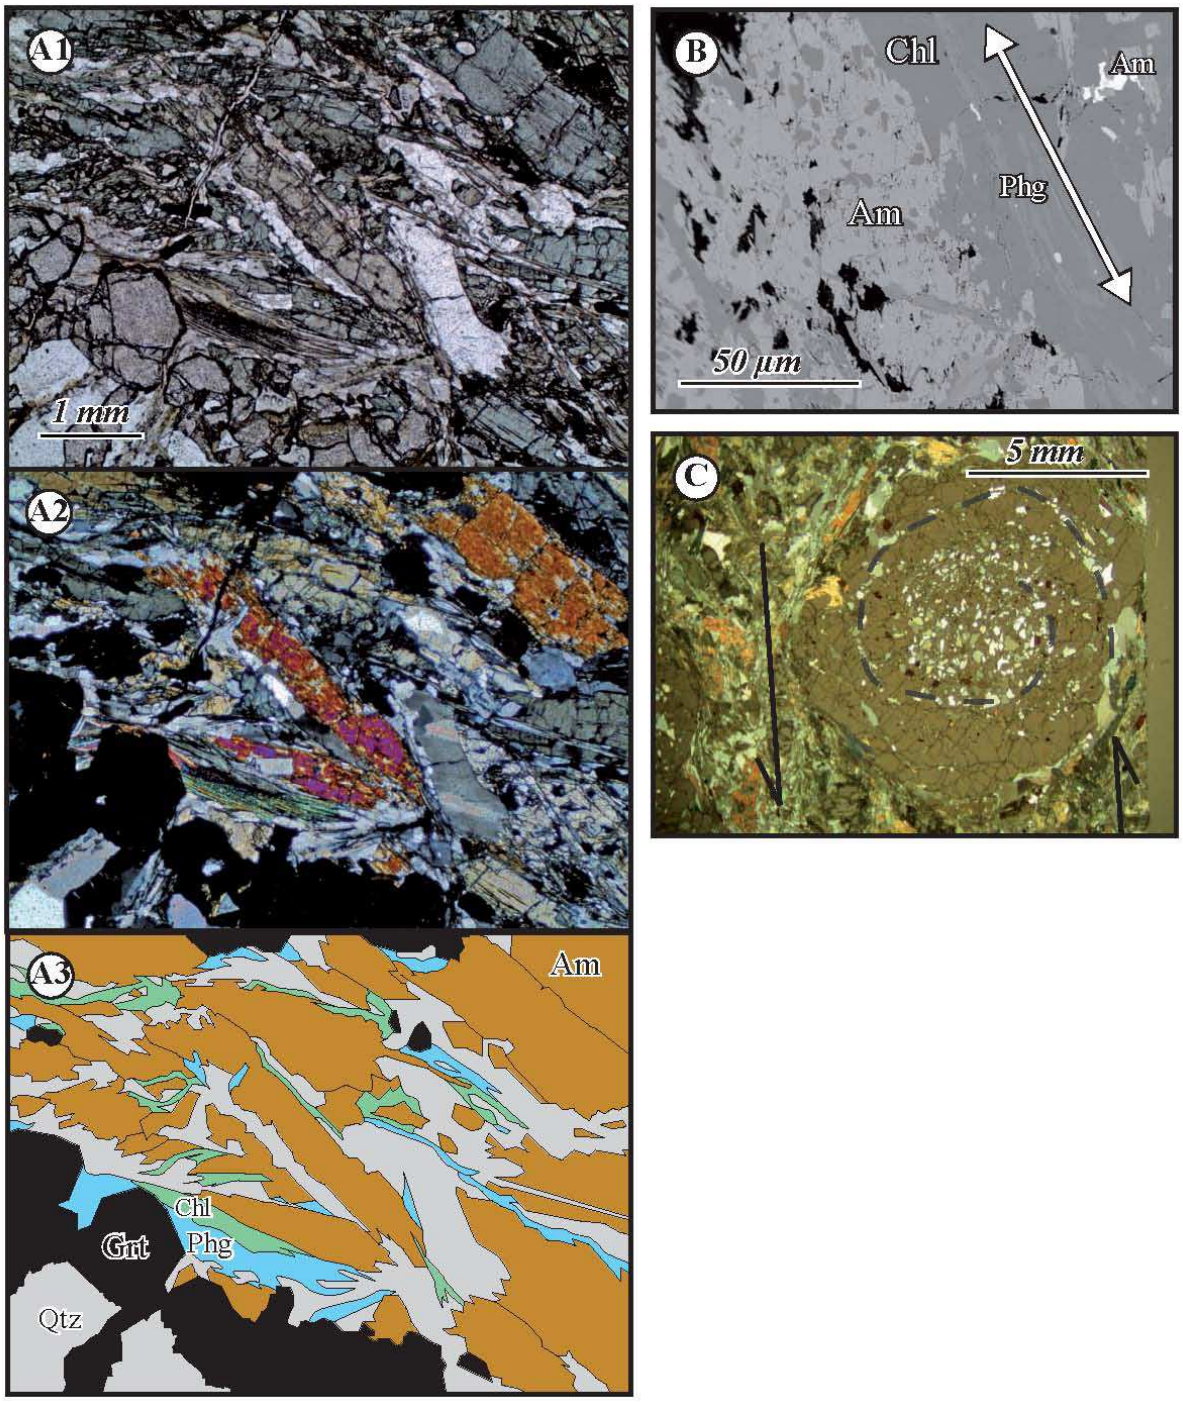

Figure 28 - (A1) and (A2), photographs of a thin section of garnet amphibolite sample AR-08-09c in plain and cross-polarized light, respectively. (A3), sketch of thin section photographs. Cross cutting relationships of amphiboles with micas (Phg) and chlorites (Chl) indicate the existence of amphiboles (Phg) prior to micas. This is also supported by the garnets (Grt) and amphiboles, which are molded by micas and chlorites. (B), back-scatter image of garnet amphibolite sample AR-09-08. Lineation is exhibited with the alignment of amphiboles (Am), white micas (Phg) and chlorites (Chl). (C), microscope photography of garnet amphibolite sample AR-09-09. The garnet is rolled in response to syn-kinematic growth during shearing.

2.4 Geochemistry

The ophiolite lithologies have already been linked to the other Lesser Caucasus ophiolites, namely the Stepanavan, Sevan and Vedi ones, and NE Anatolian ophiolites (Refahiye, Şahvelet and Karadağ) (Hässig *et al*., 2013; 2014). The different ophiolites may represent one major obduction (Galoyan *et al*., 2009; Rolland *et al*., 2009b; 2010; Yılmaz *et al*., 2013).

Two rock groups were analyzed: (1) magmatic rocks (basalt, gabbro and plagiogranite) from the preserved ophiolite unit and (2) metamorphic rocks (garnet-amphibolites) from the tectonic mélange, which leads to the identification of two distinct geochemical tendencies (**Figure 29**; **Table 5**). Analytical procedures may be found in Annexe 1.

2.4.1 Supra-subduction tholeiitic signature

As already evidenced in previous works (Hässig *et al*., 2014 and references therein) tholeiitic (MORB-type) affinity is found for the gabbro samples with, to a lesser extent, some fertile contamination as for some basalt samples, with slight trace element variations indicative of a supra-subduction environment (**Figures 29A**, **B**, **C** & **D**). Negative Eu and Ti anomalies with relative Nb-Ta depletion, is interpreted as resulting from the melting of mantle source contaminated by subduction fluids. The ophiolite assemblage is suggestive of an oceanic crust in a back- or fore-arc basin position.

Similarly to those unmetamorphosed ophiolitic rocks, the analyzed Stepanavan amphibolite from the sub-ophiolitic metamorphic rocks has a tholeiitic affinity, mainly characterized by enrichments in LILEs (e.g., Ba, Th, U) and negative Nb, Zr, and Sr anomalies which also resemble those of subduction-related arc volcanics (Perfit *et al*., 1980; Pearce *et al*., 1984). It is possible that these amphibolites share a common origin as ophiolite.

Figure 29 - Diagrams of Amasia and Stepanavan ophiolitic rocks. (A), Ti/Y versus Nb/Y (after Pearce 1982). (B), Zr/Ti versus Nb/Y rock classification diagram (after Pearce, 1996). (C), Ta/Yb versus Th/Yb diagram (after Pearce, 1982) for source characteristics for ophiolitic and associated rocks of the Amasia and Stepanavan ophiolites. (D), N-MORB normalized multi-element spider diagrams. Normalizing values are from Sun and McDonough (1989). Locations of samples of the Amasia ophiolites are found on Fig. 25, as well as results of geochemical ICM-MS analyses in Table 5.

2.4.2 Alkaline signature

The second affinity is represented by rocks with an alkaline basalt composition (i.e. Hässig *et al*., 2014) (**Figure 29A**, **B**, **C** & **D**). The garnet bearing amphibolites of Amasia Stepanavan blueschists have a similar composition to alkaline basalts, which may suggest a similar origin. For all these rocks, the diagrams are consistent with an OIB signature. In particular, the samples show neat depletions in HREE, which is ascribed to a source containing garnets (e.g., Rollinson, 1993).

The geochemical characteristics and age of the Amasia ophiolite suggest a formation in a marginal basin at Jurassic times in a supra-subduction zone setting (fore- or back-arc). Further, the similar ages and compositions concerning the obducted ophiolites onto the SAB strongly suggest that these are scattered relics of a major obduction event.

In N-MORB normalized multi-element spidergrams (**Figure 29D**) the alkaline amphibolite and blueschist samples display patterns with enrichments in incompatible elements and slightly negative Nb and Sr anomalies. These patterns are consistent with those of typical ocean island basalts (Sun and McDonough, 1989). Such a setting has already been documented by Galoyan *et al*. (2007, 2009) and dated at 117 Ma for alkali pillow lavas in the Vedi area (Rolland *et al*., 2009b).

2.5 Petrography and mineral chemistry

Two parageneses have been identified in the garnet bearing amphibolites after optical microscope observations (**Figure 28**), comprising of (1) an amphibolite facies paragenesis (amphibole-plagioclase-garnet), and (2) a retrogressive greenschist facies paragenesis (white mica-chlorite). In the following, mineral name abbreviations are following Kretz (1983). Analytical procedures may be found in Appendix S1.

2.5.1 Amphibolites

The amphibolites paragenesis found in the rocks of the kilometer-scale garnet-amphibolite lens included in the mélange, underlaying the obducted ophiolite, are characterized by garnet, amphibole, rutile and plagioclase (**Figure 28**).

The *garnets* are polyhedral, globular, millimetric to centimetric in size with numerous quartz inclusions. The inclusions found in some garnets are arranged along a ‘snow-ball’ spiral pattern (**Figure 28C**), evidencing growth during simple shear deformation. Garnets are

intensely fractured and corroded. Fractures and rims are infilled and molded by phengites and chlorites. Microprobe analyses (**Table 6**; **Figure 30A**) show that garnets are solutions of almandine (57.8 to 68.6 %), pyrope (8.1 to 32.9 %), grossular (7.3 to 27.6 %) and spessartite (0.05 to 5.1 %) end members. Two tendencies have been identified: low pyrope (AR-08-09c and AR-09-09) and low grossular compositions (AR-09-08). Transects do not evidence any significant zoning in the garnets (**Figure 30B**). These observations imply that the garnets have grown syn-kinematically under relatively homogenous pressure and thermal conditions throughout their crystallization.

The *amphiboles* of the Amasia amphibolites underline the foliation (**Figure 27C**, **27D**, **28A**). These minerals are fractured. The amphiboles are molded as well as cross-cut by phengite and chlorite. They have fairly homogenous compositions (**Table 7**; **Figure 30C**). A slight increase of Fe and Ca to the detriment of Mg is observed form core to the mineral edges. These only minor variations indicate that the amphibole crystallization occurred in almost constant pressure and temperature conditions. The amphiboles observed are all of high temperature type, and are of intermediate compositions between barroisite, pargasite, tschermakite and edenite poles (Leake *et al*., 1997). The amphiboles being in textural equilibrium with the garnets, we argue for their common formation in a high temperature context.

Rutiles are found in all the amphibolites. They are associated with the different mineral phases. Many of them have a dark aureole of ilmenite, formed during a stage of retromorphosis. The scarce plagioclases are of intermediate composition (between oligoclase and andesine). Both rutiles and plagioclases are in textural equilibrium with amphiboles and garnets.

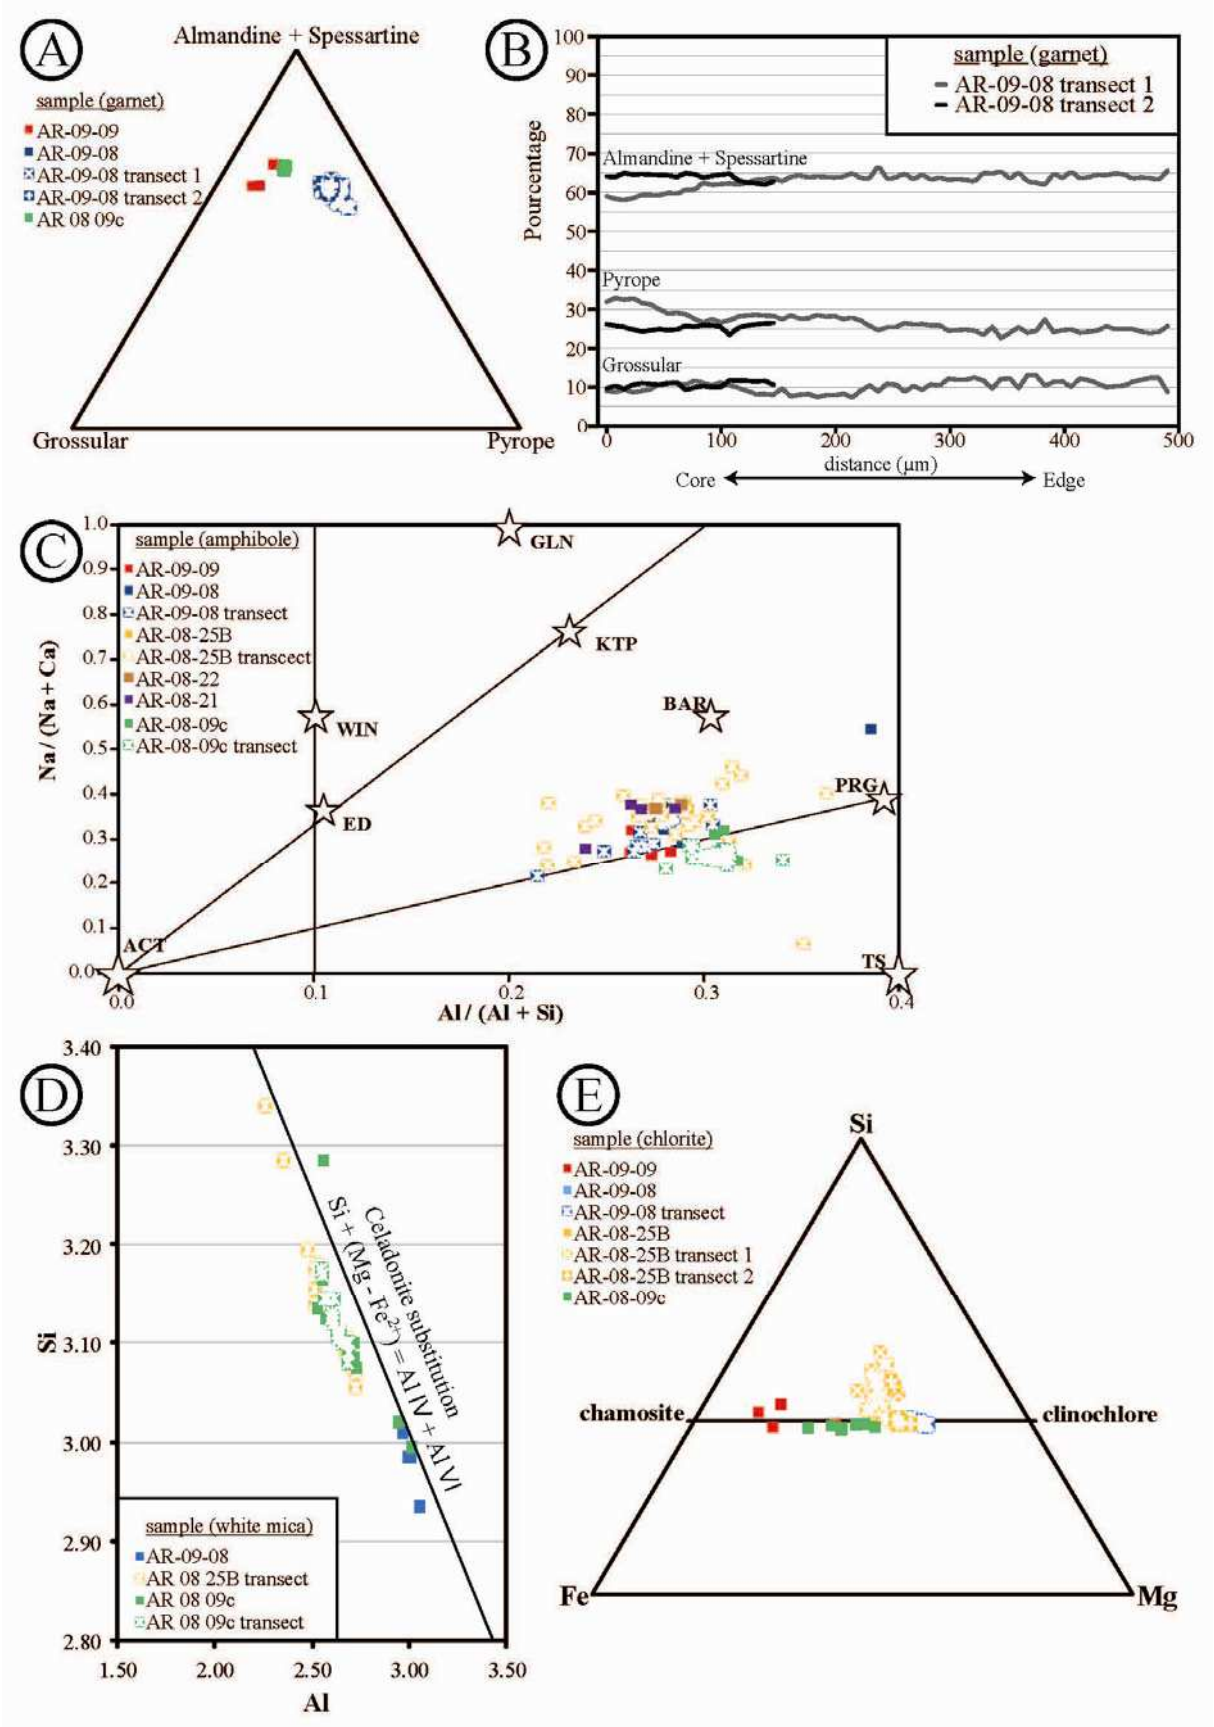

Figure 30 - Diagrams of analyzed of Amasia garnet amphibolite minerals. (A), triangular plots showing chemical compositions of Amasia amphibolite garnets. (B), compositional profiles of two garnets of the Amasia amphibolites.

Note that the garnets are relatively homogenous in composition from core to rim. (C), Na/Ca+Na vs. Al/Al+Si ratios of amphiboles from amphibolite samples, abbreviations are according to Kretz (1983). (D), Si versus Al in white micas from amphibolite samples. (E), triangular plots showing chemical compositions of Amasia amphibolite chlorites. Locations of samples are indicated on Figure 25, as well as EPMA results in Tables 6, 7, 8 & 9.

2.5.2 Greenschists

The greenschist facies paragenesis is evidenced by the presence of chlorites, epidotes and white micas. The chlorites, epidotes and phengites most often wrap and mold the amphiboles and garnets, while chlorites and epidotes consume the amphiboles throughout their growth (**Figures 28A** & **B**), which suggests the following reaction:

$$Amph + Grt + Pl + H_2O \rightarrow Ep + Chl + Phe + Qtz \quad (1)$$

The analyzed chlorites (**Table 8**) mostly range at intermediate X_{Fe} [Fe/(Fe+Mg)] contents ($0.57 < X_{Fe} < 0.78$) (**Figure 30E**).

The white micas are phengitic. They are intermediate solid solutions of muscovite and celadonite with a level of Si^{4+} substitution varying between 2.94 and 3.34 p. f. u. and a mean value of 3.12 ± 0.07 (**Figure 30D**; **Table 9**). In laboratory experiments, the Si content of phengite increases progressively with increase in pressure (Velde, 1965; Massonne and Schreyer, 1987; Domanik and Holloway, 1996; 2000). These compositions agree with crystallization of the phengites during a relatively short stage of the PT evolution as evidenced by low standard deviation for analyses of Si substitution. Locally, paragonites are interlayered within the phengites.

2.6 Pressure-Temperature path of the Amasia amphibolites

The Pressure (P) - Temperature (T) history is investigated using pseudosection modeling as well as thermo-barometric calibrations using mineralogical and whole-rock composition of the sample AR-08-09c, which has been dated by $^{40}Ar/^{39}Ar$ on amphibole and phengite (see section $^{40}Ar/^{39}Ar$ Dating). Supplementary samples (AR-08-25B, AR-09-08 and AR-09-09) have been selected to investigate the degree chemical and PT variability within the amphibolite unit.

2.6.1 Perpl_X pseudosection modeling

The pressure and temperature conditions of amphibolite facies paragenesis were investigated using pseudosection modeling performed in SiO_2-Al_2O_3-FeO-MgO-CaO-Na_2O-K_2O-TiO_2 system and calculated with Perple_X 6.6.6 (Connolly, 2009), using the internally consistent thermodynamic database of Holland and Powell (2003) and Connolly and Kerrick (2002). Solution models used are chlorite [Chl(HP)], phengite [Pheng(HP)], garnet [Gt(HP)], plagioclase [Pl(h)], amphibole [GlTrTsPg] and orthopyroxene [Opx(HP)] (solution model references available at http://www.perplex.ethz.ch/PerpleX_solution_model_glossary.html). Average bulk compositions used as model input are given in **Table 5**. NaCaKFMASH P-T pseudosection for this sample of garnet amphibolites is presented for this bulk composition in **Figure 31A**. Mineral abbreviations used are those of Kretz (1983).

In order to better constrain P-T conditions of the garnet-amphibole paragenesis, Al p.f.u. isopleths in amphiboles were calculated using EPMA amphiboles analyses (**Table 7**). In view of fairly homogenous EPMA compositions of amphiboles, constraints were brought to the model. The resulting domain corresponds to Al content ranging from 1.55 to 1.65 p.f.u., which corresponds to HT-LP metamorphic conditions ($T>625°C$ and $5.5<P<6.8$ kbar) for the first garnet- amphibole paragenesis.

2.6.2 Thermobarometric calibrations

Two parageneses are texturally identified: the first HT one is featured by the stability of amphibole and garnet, while the second lower temperature one is featured by chlorite and phengite overgrowths. For the first paragenesis garnet–amphibole geothermometry (Perchuk *et al*., 1985) was used to constrain the thermal conditions of the HT-LP assemblage. An advantage of using partitioning of Fe and Mg between garnet and coexisting ferromagnesian minerals in metamorphic rocks lies in their significant variation with temperature (Råheim and Green, 1974; Ferry and Spear, 1978; Krogh and Råheim, 1978; O'Neill and Wood, 1979; Ellis and Green, 1979; Green and Hellman, 1982; Graham and Powell, 1984) and the independence of these calculated temperatures with the fugacities of volatile species throughout metamorphism. Representative EPMA analyses of garnet and amphibole mineral phases were used. Garnet and amphibole oxide percentages were acquired from a polished thin section of samples AR-08-09c, AR-09-08 and AR-09-09 (**Tables 6** & **7**). The results are plotted as frequencies of temperatures obtained for combinations of amphibole-garnet pairs on

Figure 31B. The resulting calculated temperatures of 625~675°C validate and precise the thermal conditions calculated using Perpl_X thermodynamic modeling.

2.6.3 Phengite-Quartz-H_2O thermometry

The second paragenesis, formed in the greenschist facies, overprints the amphibolite facies (garnet+amphibole) paragenesis. In order to evaluate the P-T conditions of this greenschist facies retrogression the phengite–quartz–water method documented by Dubacq *et al*. (2010) was applied to each phengite EPMA analysis acquired in samples AR-08-09c, AR-08-25B and AR-09-08. Dubacq *et al*. (2010) showed that the mica–quartz–water equilibrium could be used as a barometer at given temperature conditions. For each phengite analysis a divariant P–T line, along which the interlayer water content varies, was calculated; the results are plotted in **Figure 31C**. The P-T lines depict geothermal gradients ranging from 10 to 45 °C/km with bulk spread along 20 ± 5°C/km.

In order to better constrain P-T conditions of the greenschist paragenesis, Si p.f.u. isopleths in phengite were calculated and plotted with the phengite EPMA analyses of dated sample AR-08-09c (**Table 9**) using Perpl_X thermodynamic modeling. In view of fairly homogenous EPMA compositions of phengites, constraints were brought to the model. The resulting domain (**Figure 31D**) corresponds to Si^{4+} content equal to or inferior to 3.14 p.f.u., in agreement with the mica-quartz-water calibrations. Resulting values (T = 580~620°C and P = 8~10 kbar) are in agreement with MT-MP metamorphic conditions featuring a thermal retrogression at slightly higher pressure of the former amphibolite-facies minerals.

In conclusion, the two metamorphic steps are relatively close in the P-T space. They suggest an anticlockwise PT path (**Figure 33**) at slightly higher temperature and lower pressure conditions than neighboring Stepanavan blueschists (Rolland *et al*., 2009a).

2.7 $^{40}Ar/^{39}Ar$ Dating

Geochronology was undertaken by single-grain laser $^{40}Ar/^{39}Ar$ dating on different mineral phases, amphiboles and white micas for amphibolites and green-schists parageneses, respectively. Detailed results may be found in **Annexes 4**, **5**, **6** and **7**.

2.7.1 Dating of amphiboles

The amphibole from the sample AR-09-08 (K390) yielded a plateau age of 87.7 ± 2.8 Ma with a MSWD of 0.06 (**Figure 32A**),computed with the last three heating steps (94.7 % of released ^{39}Ar) The inverse isochron age is 86.0 ± 7.0 Ma with a MSWD of 0.02, in agreement with the plateau age.

The amphibole from the sample AR-09-15 (K402) yielded a plateau age of 91.2 ± 1.6 Ma with a MSWD of 0.59 (**Figure 32B**) computed with six out of seven heating steps pertaining 98.0 % of total released ^{39}Ar. The inverse isochron age is 89.3 ± 3.8 Ma (1σ) with a MSWD of 0.74, in agreement with the plateau age.

The amphibole from the sample AR-08-09c (K427) yielded a plateau age of 90.3 ± 1.5 Ma with a MSWD of 0.01 (**Figure 32C**) computed with the last five heating steps representing 92.8 % of total released ^{39}Ar. The inverse isochron age is 90.2 ± 1.9 Ma with a MSWD of 0.01, in agreement with the plateau age.

In conclusion, the three amphibole $^{40}Ar/^{39}Ar$ ages agree with a common crystallization age during the amphibolite HT peak at about 90 ± 0.5 Ma.

Figure 32 - $^{40}Ar/^{39}Ar$ age, Ca/K spectra and inverse isochrones. (A), amphibole from sample AR-09-08. (B), amphibole from sample AR-09-15. (C), amphibole from sample AR-08-09c. (D), white mica from sample AR-08-09c. Locations of samples are shown on Fig. 25. (E), compilation of ages which may also be found in Table 10, as well as detailed dating results in supplementary data files.

2.7.2 Dating of phengites

The phengite from the sample AR-08-09c (K428) yielded a plateau age of 89.7 ± 0.7 Ma with a good MSWD of 0.80 (**Figure 32D**) computed with the last seven heating steps representing 97.0 % of the total ^{39}Ar gas freed during the whole analysis. The inverse isochron overlaps within 1σ error the plateau age.

This age indicates that the MP-MT chlorite-phengite paragenesis age is similar within error to the amphibolite HT peak age obtained above, and likely occurred between 89 and 90 Ma.

In conclusion of the $^{40}Ar/^{39}Ar$ dating section, the amphibole and phengite $^{40}Ar/^{39}Ar$ ages obtained on Amasia amphibolites are similar within error. They agree with a crystallization during a rapid metamorphic cycle related to oceanic crust obduction at about 89-90 Ma (**Figures 32E** & **33**), at the beginning of the Late Cretaceous (Turonian), just prior to paleontological dating obtained at the front of Armenian ophiolites obduction (89-83 Ma; Sosson *et al*., 2010).

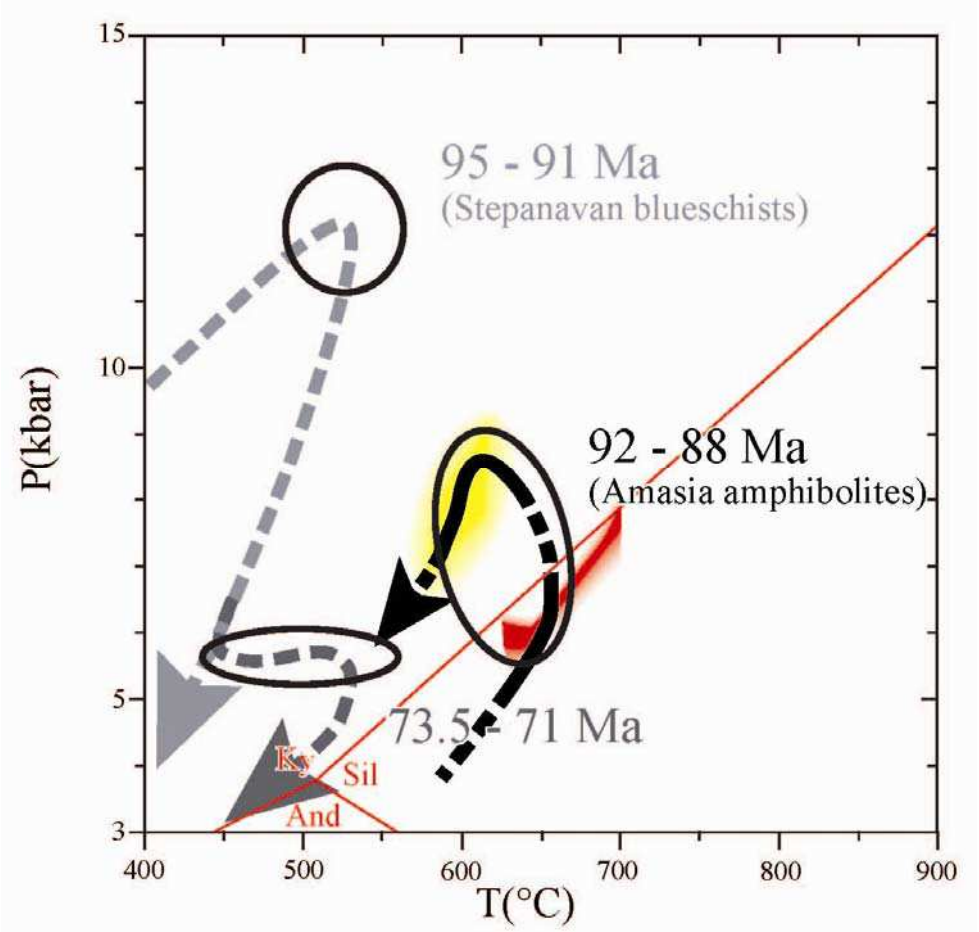

Figure 33 - Compilation of determined PT-t paths for the Amasia-Sevan-Akera metamorphic rocks found in basal position of ophiolite bodies inferred through this study of the outcrops of Amasia garnet amphibolite in black and Stepanavan blueschist (Rolland *et al*., 2009a) in grey.

2.8 Discussion

The study of the metamorphic rocks found under ophiolites provides key data for the understanding of obduction processes (e.g., Wakabayashi and Dilek, 2000; Gaggero *et al*., 2009). The so-called 'metamorphic sole' of obducted ocean lithosphere recorded variations in temperature and pressure throughout processes ranging from intra-oceanic subduction to obduction due to the progression of a relatively cold sinking slab and hot overriding plate and yields insights into the obduction dynamics (e.g., Coleman, 1981; Agard *et al*., 2010). Such examples are widespread in Anatolia (Whitechurch *et al*., 1984; Collaku *et al*., 1991; Robertson and Karamata, 1994; Abd El-Naby *et al*., 2000; Al-Riyami *et al*., 2002; Çelik and Delaloye, 2003; 2004; 2006; Beccaletto and Jenny, 2004; Çelik *et al*., 2006; Çelik, 2007). In the following discussion we argue for the presence of a single and major ophiolite nappe in the Lesser Caucasus region, based on a comparison of geochemical, mineral and geochronological data of the various ophiolite outcrops. Further, based on the PTt history of

underlying 'metamorphic sole' rocks, we propose a reconstruction of the obduction history in this region.

2.8.1 Evidence for one large ophiolite nappe obducted in the Lesser Caucasus

The similarity of the Amasia ophiolite petrology with the other Armenian and NE Turkey ophiolites reinforces the model of a single ophiolitic nappe obducted over the Taurides-Anatolides (Yılmaz *et al*., 2013; Hässig *et al*., 2014 and references therein). The geochemical and geochronological features are the following (**Figure 29**):

Sample geochemistry is marked by depletions in Nb–Ta, and LILE enrichments, which is in agreement with a formation context involving contamination of slab-derived fluids due to supra-subduction contamination (Hässig *et al*., 2013). Since a full ophiolitic lithological assemblage was described in Armenian ophiolites (comprising radiolarites, pillow basalts, gabbros, plagiogranites and serpentinites), in the corresponding geodynamic context is a marginal basin environment (fore- or back-arc). The main problem in the determination of the relative position of this marginal basin in terms of fore- or back-arc is the unknown position of the former volcanic arc that ought to be formed. In Armenia, the presence of meta-volcanites in the blueschist units found below the obduction contact in Stepanavan (Rolland *et al*., 2009b) suggests that the arc was accreted to, and subducted with, the sinking slab. Thus, the basin would have been in a back-arc position. However, the question still remains. The most likely polarity for the former intra-oceanic subduction zone is north dipping, south of the marginal basin. This is suggested by the overall north verging tectonic pile, comprising in the SAB, the ophiolite and the Eurasian margin (**Figures 24** & **27B**). Such a geometry is also observed in the other ophiolite outcrops in both Armenia and NE Anatolia (e.g. Hässig *et al*., 2014 and references therein).

Field investigations systematically evidence alkaline OIB type basalts topping the ophiolite sections in the Lesser Caucasus (Galoyan *et al*., 2007; 2009; Rolland *et al*., 2009b). In Turkey, alkaline rocks are also associated to the ophiolites (Refahiye and Karadağ volcanites; Parlak *et al*., 2012). These alkaline rocks have been dated at c. 117 Ma by the $^{40}Ar/^{39}Ar$ method on amphibole (Rolland *et al*., 2009b). Thus, OIB formation occurred prior to the obduction of the oceanic crust. An alkaline (OIB) tendency is 0observed for some of the metamorphic rocks found directly under the ophiolites as well. The geochemical composition

of the Amasia garnet amphibolites from the metamorphic unit beneath the ophiolite shows a similar alkaline tendency as the alkaline suite described on top of the Armenian ophiolite. Subophiolitic amphibolites and blueschists from elsewhere along the northern Neotethys suture have compositions indicative of different volcanic suites protoliths (MORB, WPB, and IAT) which were stacked together during intra-oceanic subduction in a Neotethyan basin (Lytwyn and Casey, 1995; Parlak *et al*., 1995; Çelik and Delaloye, 2003; Vergili and Parlak, 2005; Çelik and Delaloye, 2006; Parlak *et al*., 2006; Elitok and Drüppel, 2008). The alkaline tendencies found in the metamorphic rocks may be interpreted as being relics of seamounts and/or oceanic plateaus emplaced on the subducting oceanic plate, later overthrusted by the ophiolite. Another interpretation is that these tendencies represent pieces of the ophiolite from the upper plate, which itself comprises of different geochemical tendencies. Following this hypothesis, the upper plate oceanic lithosphere was dismembered and incorporated to the sole lithologies as the ophiolite progressed throughout subduction and obduction processes (e.g. Whitechurch *et al*., 1984; Jaillard *et al*., 1997; Wakabayashi and Dilek, 2003; Huene *et al*., 2004; Sage *et al*., 2006; Yamamoto *et al*., 2009).

The Izmir–Ankara–Erzincan–Sevan–Akera ophiolite obduction appears to be amongst most exceptional cases of obductions. Due to similar tectonic settings, emplacement ages, and to the presence of similar geochemical compositions and similar Jurassic ages (e.g. Çelik *et al*., 2011; Topuz *et al*., 2013a; 2013b; Uysal *et al*., 2013) for the ophiolite belt into NE Anatolia, along the Ankara–Erzincan suture zone further west, we propose that this obduction connects to the basal contact of the NE Turkish ophiolite (following Hässig *et al*., 2014 and Yılmaz *et al*., 2013). Such correlation suggests an obducted ophiolitic nappe of at least 700 km in length and up to 300 km in width along the Ankara–Erzurum–Sevan–Akera suture zone on top of the Tauride Block continuing laterally to the SAB.

2.8.2 Model for the initiation and propagation of the Lesser Caucasus obduction

From all the available geological data, particularly with new PT-t data from the amphibolites of the Amasia ophiolite metamorphic sole, we propose the following model for the evolution of the northern branch of Neotethys (**Figure 34**):

1- The magmatic rocks of the Amasia ophiolites, along with correlated Lesser Caucasus and NE Anatolia region share similar geochemical signatures influenced by a subduction

component in an oceanic basin environment (Hässig *et al*., 2014). These data argue for simultaneous crust formation in a supra-subduction setting in the Middle to Upper Jurassic times.

2- Two north dipping subduction zones are evidenced by simultaneous magmatism on the Eurasian active margin and in the intra-oceanic setting, responsible for the formation of the Supra Subduction Zone type ophiolite bodies (e.g., Rolland *et al*., 2010; Sosson *et al*., 2010). The later intra-oceanic subduction is argued to likely evolve into an obduction contact accountable for ophiolite emplacement at the arrival of the SAB in the subduction zone.

3- Two magmatic suites were emplaced one on top of the other: (1) a gabbroic basement of thinned back-arc oceanic crust, (2) topped by thick basaltic flows with an alkaline tendency. The presence of identical alkali basalts in similar stratigraphic positions strongly favors the formation of several oceanic islands or one large plateau related to hot spot magmatism (e.g., Galoyan, 2008). Observations undertaken in the Amasia area are thus compatible with a model of obduction of a Supra Subduction Zone ophiolitic domain through intra-oceanic subduction and active oceanic margin slicing after OIB emplacement (**Figure 34**). This model explains the position of alkaline rocks both underneath, as sheared lenses occur in the mélange, and also above ophiolite as pillow lavas. The alkaline outcrops would have been under-thrusted during intra-oceanic subduction or during emplacement of the overriding ophiolite bodies.

4- The flysch deposits give an upper temporal limit to the obduction of this oceanic crust in Santonian times (84-83 Ma). Paleontological dating undertaken on the flysch in Amasia, Sevan and Vedi indicates similar dates (Sosson *et al*., 2010, Hässig *et al*., 2013), which agrees for a fast obduction process dragging the deep metamorphic sole on top superficial rocks within 6 to 7 Ma.

5- Considering the hypothesis of ophiolite formation during intra-oceanic subduction, a problem is posed by the absence of the volcanic arc in Armenia. There, theonly evidence of such an island arc can be found in the ophiolitic sole through the geochemical composition of metamorphic rocks. Two hypotheses on the disappearance of this arc may be proposed: (1) the alteration and erosion of the volcanic arc by uplift during the obduction or (2) the accretion and subduction of the fore-arc block and dragging of the volcanic arc with it, as proposed by Shemenda (1994) in his analogical model of subduction. This latter model is preferred based on (1) the presence of some volcanic blocks in the Stepanavan blueschists in Armenia. There, it is hypothesized that the Stepanavan blueschists correspond to the missing

volcanic arc dragged into the subduction zone (Galoyan *et al*., 2007; Rolland *et al*., 2009a) (**Figure 34**). (2) More to the west, in northeastern Turkey, remnants for such intra-oceanic subduction, including eclogites, have been found (Topüz *et al*., 2013a; 2013b, Uysal *et al*., 2013). In the Erzincan region bibliographic data as well as field observations (Hässig *et al*., 2014) lead to further argue this hypothesis by the presence of low-grade metamorphic rocks of volcanic origin. This outcrop reveals metamorphic rocks with calc-alkali tendencies overthrusted by ophiolitic rocks from North to South along the northern edge of the Erzincan basin (Gücer *et al*., 2007; Aslan *et al*., 2011). Therefore, the absence of the volcanic arc formed above the intra-oceanic subduction may be explained by its accretion to the subducting slab and its dragging under the obducting ophiolite through scaling by faulting and tectonic erosion into the subduction channel, gradually evolving into an "obduction channel" due to variations in sinking slab dip.

2.8.3 Significance of the counterclockwise PTt path

The counterclockwise PTt path that is obtained for the Amasia amphibolites coincides with clockwise the PTt path of neighboring Stepanavan blueschists. This, together with the model of obduction initiation proposed above, suggest that:

(1) HT-LP conditions in Amasia and formation of garnet amphibolites, is due to obduction initiation in the back-arc domain within the thinned oceanic crust, significantly heated by the emplacement of hot-spot series at c. 117 Ma.

(2) MP-LT conditions during the chlorite-phengite retrogression of garnet amphibolites are ascribed to intercalation in the subduction channel with the blueschists.

(3) Common exhumation process after the MP-LT conditions of the blueschists and amphibolites explain their similar tectonic position. In this scenario, the slices of metamorphic rocks represent relics of subducted oceanic and volcanic arc lithosphere (Stepanavan blueschists). The Amasia garnet amphibolites recorded a more complex history starting from alkaline volcanic rocks originally emplaced on the seafloor, (i) underthrusted down to ~20 km below hot oceanic crust during obduction initiation in the back-arc, followed by (ii) their incorporation into the subducting slab until a depth of about 30 km in the accretionary prism (where they merge with blueschists), (iii) their exhumation within this prism (or tectonic mélange). (iv) Finally, the amphibolites and blueschists were transported into the tectonic mélange at the obduction interplate contact onto the SAB.

2.8.4 Comparisons with other obductions in the Caucasus-Arabic domain

When considering the timing of obductions in the Middle East region it appears thatthe Lesser Caucasus and Oman ophiolites were obducted within the same time span (~90 Ma) (e.g. Agard *et al*., 2010). However, preliminary paleomagnetic analyses that both ophiolites were in distinct geographical locations distant of about 1200 km; (Meijers *et al*., 2012). Further, these authors propose that a >1500 km large ocean domain till separated the SAB and TAB from the Arabian margin until Upper Cretaceous times. This ocean domain corresponds to the southern Neotethys, which likely closed during the Late Eocene times (Rolland *et al*., 2012). Thus, synchronous obductions occurred on both the northern and southern Neotethyan edges, significantly before the stages of continental subduction. Linking the history of metamorphic rocks to that of syn- to post-obduction sediments from the southerly Vedi area and paleomagnetism, gives strong arguments to infer that at the end of the obduction event (Santonian, 83-84 Ma) a residual oceanic domain (less than 1200 km) still remained to be closed north of the obduction zone before final SAB-TAP collision with the Eurasian margin (Meijers *et al*., 2013). This, in turn implies that the obduction process of preserved oceanic lithosphere is not linked to its subduction further north under Eurasia, but solely to the dynamics of the intra-oceanic subduction.

2.9 Conclusion

The petrologic study of Amasia ophiolites argues for the presence of one large obduction in the Lesser Caucasus, which occurred at Middle Cretaceous times at c. 90 Ma. The history of metamorphic rocks preserved in ophiolite 'soles', below the un-metamorphosed oceanic units, highlights an example of syn-obduction metamorphism featured by a counter-clockwise PTt path. The metamorphic rocks preserve two successive parageneses featured by (1) amphibole-garnet-plagioclase at the HT-LP peak (at P = 5.8~7.0 kbar, T = 625~675°C) and (2) a chlorite-phengite retrogression at MT-MP conditions (P = 7.8~9.8 kbar, T = 620~660°C). The increase in P is ascribed to thickening of the overriding compartment of the subduction zone at c. 90-89 Ma, as well as subsequent underthrusting of amphibolites under the future ophiolite, as the South Armenian Block enters the subduction zone. In this paper, the obduction is dated for the first time by direct $^{40}Ar/^{39}Ar$ dating on amphiboles (hornblende) and white micas (phengite) yielding for both HT and MP peaks similar within-error ages of 90 ± 0.5 Ma and 89-90 Ma, respectively. This dating accounts for a very rapid tectonic evolution featured by (1) the slicing of oceanic crust and its dragging under the obduction front below a relatively hot oceanic crust at c. 91 Ma and (2) the incorporation of the basal obduction slices within the subduction zone deep prism at 91-90 Ma. Following tectonic evolution is featured by (3) a common exhumation of blueschists + garnet amphibolites within the subduction zone (accretionary prism), and their incorporation in a greenschist facies tectonic mélange. (4) The latter is transported at the base of the obduction. Ending of obduction occurred within 1-5 Ma at c. 89-83 Ma, as shown by paleontological ages in both thrusted (sub-ophiolitic) and uncomformably overlying (supra-ophiolitic) sediments, in the Armenian foreland. Final exhumation of Amasia and Stepanavan metamorphic rocks occurred in the Eocene, during the final Arabia-Eurasia collision, as shown y Eocene unconformity on top of these rocks.

Acknowledgments

This work was supported by the MEBE and DARIUS programs coordinated by E. Barrier and M.F. Brunet from the University Pierre and Marie Curie and the INSU/CNRS. Fieldwork was facilitated by the support of the Armenian National Academy of Science

(Institute of Geological Sciences). The technical help of M. Manetti in the preparation and mineral analysis is also acknowledged along with G. Delanoy for thin sections. We wish to thank J.L. Devidal in Clermont-Ferrand, P. Capiez in Lyon and S. Gallet in Nice for their involvement during data acquisition. <u>Chapitre 3</u> - Relations entre les ophiolites du N-E de l'Anatolie et du Petit Caucase : arguments pour une obduction de grande échelle de croute océanique.

« L'ordre et la connexion des idées est le même que l'ordre et la connexion des choses. »

Spinoza, extrait d'*Ethique II*

III.1 Article 3 – Linking the NE Anatolian and Lesser Caucasus ophiolites: evidence for large scale obduction of oceanic crust and implications for the formation of the Lesser Caucasus-Pontides Arc

Une des difficultés majeures de la reconstruction des évènements géodynamiques ayant abouti à la mise en place des ophiolites dans la région du Petit Caucase-Pontides est due à l'intermittence des affleurements. En effet, un épais dépôt de sédiments et de roches volcaniques post-obduction (Eocène à Quaternaire) recouvre ces régions (Avagyan *et al.*, 2010; Gürer *&* Aldanmaz, 2002; Sosson *et al.*, 2010). Par conséquent, pour relier les domaines ophiolitiques de l'Arménie et du NE de la Turquie et valider la continuité des unités structurales principales nous cherchons à répondre à trois questions au cours de cette étude :

(1) Toutes les ophiolites du Petit Causase-NE Anatolie sont-elles des restes de la même lithosphère océanique ?

(2) Furent-elles obduites sur un ruban continental continu (comprenant les SAB et Taurides-Anatolides au sud) ?

et (3) Est-ce que ce domaine océanique fut subduit sous une même marge continentale au nord?

Nos études précédemment exposées ont montré que l'ensemble des âges de formation ainsi que les compositions des roches analysées sont similaires à ceux des autres ophiolites arméniennes (Galoyan *et al.*, 2009; Rolland *et al.*, 2009a; 2009b; Sosson *et al.*, 2010). Ceci est également vrai pour les affleurements de roches ophiolitiques en Turquie du NE (Çelik *et al.*, 2011; 2013; Topuz *et al.*, 2013a; 2013b). Ces comparaisons soutiennent l'hypothèse que l'échelle du chevauchement de lithosphère océanique sur la lithosphère continentale est exceptionnelle. Selon toute vraisemblance la ceinture ophiolitique anatolienne (suture d'Izmir-Ankara-Erzincan) se prolonge bien dans le Petit Caucase (suture de Sevan-Akera) (Knipper, 1975; Knipper *&* Khain, 1980; Adamia *et al.*, 1981; Şengör *&* Yılmaz, 1981; Adamia *et al.*, 1987; Yılmaz *et al.*, 2000; Galoyan, 2008).

Les ophiolites ont des compositions géochimiques montrant des affinités avec un contexte de supra-subduction. La composition géochimique des unités métamorphiques sous les ophiolites Stépanavan, Amasia et Erzincan a une affinité calco-alcaline à alcaline distincte,

attribuée à des processus magmatiques anté-obduction (Galoyan, 2008; Galoyan *et al.*, 2007; 2009; Rolland *et al.*, 2010; Rolland *et al.*, 2009; Sosson *et al.*, 2010). Toutefois, lorsque l'on considère un modèle dans lequel les ophiolites se forment en position supra-subduction à arrière-arc dans un contexte de subduction intra-océanique, avec une ouverture lente, les observations amènent à conclure que l'arc volcanique insulaire est manquant.

Il a été suggéré que les ophiolites sont représentatives d'un environnement avant-arc en raison de certaines signatures chimiques boninitiques (Crawford, 1989; Falloon *&* Crawford, 1991), et de l'absence de l'arc insulaire (Parlak *et al.*, 2013). Cependant, des études plus récentes ont montré que des boninites se mettent non seulement en place dans un domaine d'avant-arc, mais aussi dans des environnements d'arrière-arc (Deschamps *&* Lallemand, 2003; Falloon *et al.*, 1992; Teklay, 2006). Deschamps *&* Lallemand (2003) attribuent même les boninites davantage à un environnement d'arrière-arc. Il est possible que l'arc ait disparu au cours d'un processus d'accrétion/subduction comme le décrivent Boutelier *et al.* (2003), Shemenda (1994), et Ellis *et al.* (1999), lors de sa rencontre avec la marge continentale plus au sud. Ceci expliquerait les tendances géochimiques d'arc des roches composant la semelle de l'obduction.

Ainsi, cette nouvelle contribution à la compréhension de l'évolution géodynamique des ophiolites du Petit Caucase et du NE de l'Anatolie soutient la présence de deux zones de subduction plongeant vers le nord : (1) une sous la marge eurasienne et (2) plus au sud, une autre, intra-océanique à l'origine des ophiolites, conduisant à la mise en place ophiolite. Cela étend le modèle géodynamique proposé précédemment vers l'est pour inclure le NE de l'Anatolie, et pourrait être généralisé à l'ensemble de celle-ci.

L'ensemble des données (structurales, stratigraphiques, géochimiques et géochronologiques) provenant de toute la zone d'étude, concernant la mise en place de ces différentes ophiolites, amènent à la conclusion qu'elles appartiennent à une seule nappe ophiolitique. Cette analyse nous permet de proposer un modèle dans lequel ce domaine océanique obduit, continu d'est en ouest entre le SAB-TAP et au sud et les Pontides et Somkheto-Karabagh au nord, s'est formé et mis en place selon les mêmes modalités et dans le même intervalle de temps. Par conséquent, nous suggérons la mise en place d'une nappe ophiolitique, d'une extension latérale de plusieurs centaines de kilomètres (>600 km) et d'un rejet horizontal de 100 à 200 kilomètres, dans un modèle commund'obduction.

Cette étude a fait l'objet d'un article publié dans *Geodinamica Acta*.

Abstract

In the Lesser Caucasus and NE Anatolia three domains are distinguished from south to north: (1) Gondwanian-derived continental terranes represented by the South Armenian Block (SAB) and the Tauride-Anatolide Platform (TAP), (2) scattered outcrops of Mesozoic ophiolites, obducted during the Upper Cretaceous times, marking the northern Neotethys suture, and (3) the Eurasian plate, represented by the Eastern Pontides and the Somkheto-Karabagh Arc. At several locations along the northern Neotethyan suture, slivers of preserved unmetamorphozed relics of now disappeared Northern Neotethys oceanic domain (ophiolite bodies) are obducted over the northern edge of the passive SAB and TAP margins to the south. There is evidence for thrusting of the suture zone ophiolites towards the north, however we ascribe this to retro-thrusting and accretion onto the active Eurasian margin during the latter stages of obduction. Geodynamic reconstructions of the Lesser Caucasus feature two north dipping subduction zones: (1) one under the Eurasian margin and (2) farther south, an intra-oceanic subduction leading to ophiolite emplacement above the northern margin of SAB. We extend our model for the Lesser Caucasus to NE Anatolia by proposing that the ophiolites of these zones originate from the same oceanic domain, emplaced during a common obduction event. This would correspond to the obduction of non-metamorphic oceanic domain along a lateral distance of more than 500 km and overthrust up to 80 km of passive continental margin. We infer that the missing volcanic arc, formed above the intra-oceanic subduction, was dragged under the obducting ophiolite through scaling by faulting and tectonic erosion. In this scenario part of the blueschists of Stepanavan, the garnet

amphibolites of Amasia and the metamorphic arc complex of Erzincan correspond to this missing volcanic arc. Distal outcrops of this exceptional object were preserved from latter collision, concentrated along the suture zones.

Keywords : Lesser Caucasus; NE Anatolia; Tethys; Ophiolite; Obduction

1.1 Introduction

During the Mesozoic, the southern margin of the Eurasian continent was involved in the closure of Paleotethys and the opening of Neotethys oceans. Later, from the Jurassic to the Eocene, subductions, obductions, micro-plate accretions, and finally continent-continent collision occurred between Eurasia and Arabia, and resulted in the closure of Neotethys.

In order to better understand the different phases linked with the opening and closing of the Tethyan Ocean leading to the current structure of the Lesser Caucasus and the Eastern Pontides (**Figure 35**), it is important to identify the different units involved in the Tethyan suture *s.l.* and their corresponding geodynamic context including the lateral continuation of the structures. The evolution of northern Neotethys can be deduced from the structural, geochemical and geochronological studies of preserved oceanic crust domains obducted (ophiolites) in the Lesser Caucasus and in NE Anatolia and of the metamorphic rocks beneath these ophiolites. These studies yield key time and paleogeographic data from the East Mediterranean area to the NW Himalayan belt (Barrier & Vrielynck, 2008; Dercourt et al., 1986; Galoyan et al., 2009; Hafkenscheid et al., 2006; Hässig et al., 2013; Okay & Tüysüz, 1999; Ricou, 1994; Ricou et al., 1985; Robertson, 2004; Rolland et al., 2010; Şengör & Yılmaz, 1981; Sosson et al., 2010; Stampfli et al., 2001). Supra-subduction zone (SSZ) ophiolites provide chronologic constraints related to oceanic crust formation by repetitive extension in a fore- and/or back-arc context, linked to the behavior of an intraoceanic subduction, by the dating of related magmatic rocks. The study of these remarkable objects also contributes to understand oceanic closure, particularly ophiolite emplacement processes, by the dating of metamorphic rocks underlying the preserved (non-metamorphic) ophiolites and post-accretionary sedimentary series unconformably overlying the suture zone. Datings undertaken along the Ankara–Erzincan–Sevan-Akera suture zone suggest a similar Lower to Middle Jurassic age of the oceanic crust of c. 180-150 Ma (Çelik et al., 2011, 2013; Dilek & Thy, 2006; Galoyan, 2008; Galoyan et al., 2009; Hässig et al., 2013; Rolland et al., 2009b, 2010; Topuz et al., 2013a). A major difficulty in Mesozoic geodynamic reconstruction of the Lesser Caucasus-Eastern Pontides is the paucity of outcrops due to thick post-obduction (Eocene to Quaternary) deposit of sediments and volcanics that overly the ophiolitic nappe (Avagyan et al., 2010; Gürer & Aldanmaz, 2002; Sosson et al., 2010). Therefore, to link the NE Turkey and Armenia ophiolitic domains, three questions are posed in this study concerning the continuity of the main structural units: (1) are all the NE Turkey–Armenia ophiolites remnants of the same oceanic lithosphere, (2) are they partly obducted over a

continuous continental ribbon (including the South Armenian and Tauride-Anatolide blocks to the south), and (3) does the oceanic domain subduct under a common margin?

In this paper we present field geological, structural and whole-rock geochemical data on the crustal rocks of the NE Anatolian and Armenian ophiolites. These data in conjunction with those from the literature strongly suggest a common origin and Late Cretaceous emplacement onto the leading edge of the passive continental margin leading to the current positioning of NE Anatolian and Lesser Caucasus ophiolites.

1.2 Previous works across the NE Anatolia-Lesser Caucasus region

1.2.1 Lesser Caucasus

Previous geological, petrological and geochemical works on the Lesser Caucasus ophiolites were carried out mostly during the 1970s and 1980s (Adamia et al., 1981; Knipper, 1975; Knipper & Khain, 1980; Knipper & Sokolov, 1977; Knipper et al., 1986, 1997; Satian, 2005; Sokolov, 1977; Zakariadze et al., 1983, 1990, 2005). These works mainly showed a Jurassic age for the ophiolite bodies, and variable geochemical affinities (ranging from tholeiitic to calc-alkaline and alkaline), which was interpreted as a complex oceanic context with variable magmatic sources, and closed mainly by subduction in the Late Cretaceous (e.g., Zakariadze et al., 1990). More recent works along the Neotethys domain evidence processes which include Neotethyan oceanic crust obduction and the collision–accretion of microplates to the Eurasian margin before the final Arabia–Asia collision or India-Asia collision (Agard et al., 2010; Avagyan et al., 2010; de Sigoyer et al., 2004; Ding et al., 2005; Galoyan et al., 2009; Hacker, 1991; Hacker et al., 1996; Harper et al., 1996; Okay et al., 2001; Rice et al., 2009; Rolland et al., 2009a,b, 2011, 2012; Searle and Cox, 1999; Sosson et al., 2010; Stampfli et al., 2001; Yılmaz et al., 1993). In these works, the presence of several geochemical suites in a given suture zone is interpreted as the tectonic collage of petrological slivers originating from various oceanic environments: volcanic arc, oceanic islands and seamounts, oceanic crust from Mid Oceanic Ridge (MOR) or from back-arcs.

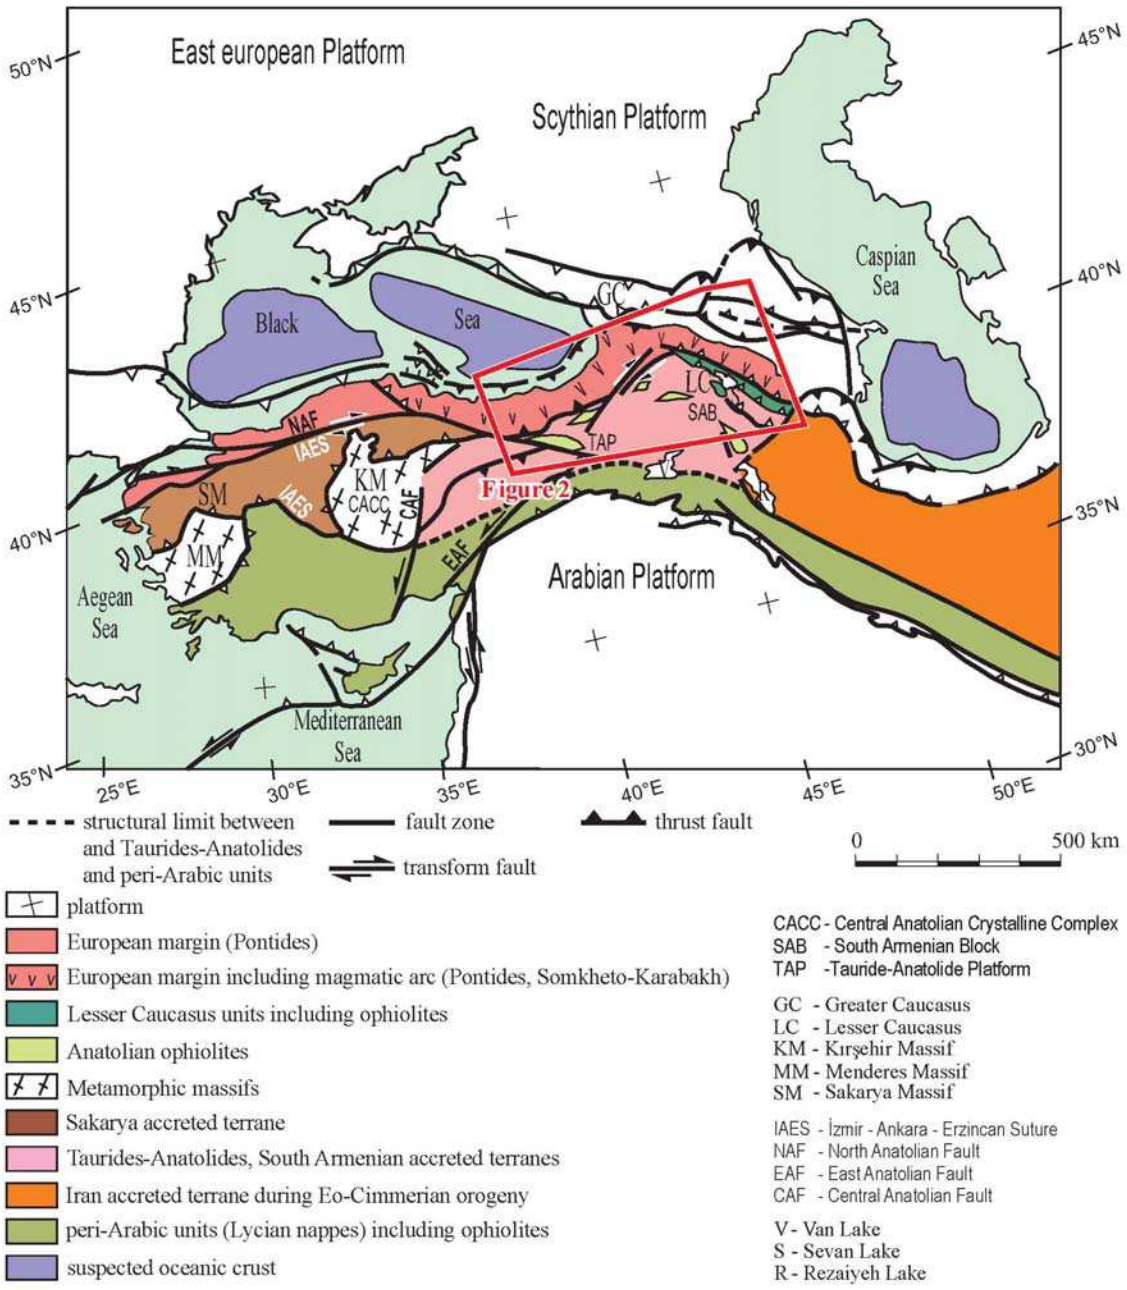

Figure 35 - Structural sketch map of the Tauride-Anatolides, Caucasus and Iranian belts (modified after Avagyan et al., 2005). Location of Figure 36 is indicated.

North of the obduction zone, in the Eurasian part of the Lesser Caucasus the subduction of the Tethys is evidenced by a thick and mainly calc-alkaline volcanogenic and volcanoclastic series of Bajocian to Santonian age (e.g., Adamia et al., 1981 for a review). At this period of time the northern Lesser Caucasus was characterized by an island arc domain called the Somkheto–Karabakh Island Arc (Adamia et al., 1977; 1987; Knipper, 1975; Ricou et al., 1986; Sosson et al., 2010). During Early Cretaceous, a part of the plutonic unit of this arc was unroofed due to tectonic erosion which was the result of significant uplift and

denudation along the subduction zone (Rolland et al., 2011). Such a change in the Eurasian active margin strain field could be, and subsequent development of this unconformity, is ascribed to the subduction of more buoyant crustal domain such as the spreading ridge of the back-arc basin (Rolland et al., 2011). The basement formations are quite similar to those known all along the Eurasian margin (Sosson et al., 2010 for a review).

South of the obduction zone, the South Armenian Block (SAB) (Knipper, 1975; Knipper & Khain, 1980) is a microplate which also corresponds to the Turkish and Iranian platforms (Şengör & Yılmaz, 1981; **Figure 35**). In Armenia the SAB is represented by a Proterozoic metamorphic basement well exposed north of Yerevan. An incomplete Paleozoic sedimentary succession (mainly represented by Upper Devonian to Upper Permian carbonates and shales) in the SW (north of the Araks Valley), widespread Triassic limestones and sandstones and some Jurassic sedimentary and volcanogenic formations unconformably covered by Cenomanian to Turonian limestone and flysch (Nalivkin, 1976; Sosson et al., 2010; **Figure 36**).

Upper Cretaceous obduction on the SAB is deduced from Upper Coniacian to Santonian flysch (reworking the ophiolites), which conformably covers Cenomanian–Turonian reef limestones and flysch of the SAB (Sokolov, 1977; Sosson et al., 2010). This obduction took place while a magmatic arc occurred along the southern edge of Eurasia (Somkheto–Karabakh island arc, Lesser Caucasus, **Figure 36**), which implies that at least two subduction zones were active at the same time (Rolland et al., 2011). The onset of collision or the continental subduction of the SAB below the Eurasian margin is dated as Late Cretaceous–Paleocene. This process occurred around 20 Ma later than the obduction (Late Coniacian–Santonian, 88–83 Ma) of the marginal basin over the SAB (Sosson et al., 2010). Oceanic closure is indicated by the Late–Middle Eocene unconformity on the SAB, the suture zone and the Eurasia margin. Ending of subduction and subsequent accretion of the SAB to the Eurasian margin resulted in the subduction jump to the south of the SAB (Rolland et al., 2012). Evidence for this southward jump in subduction can be found between the Bitlis–Pütürge massifs and SAB. There, HP metamorphic evolution due to continental subduction is bracketed between 74 and 71 Ma (Göncüoğlu & Turhan, 1984; Hempton, 1985; Oberhänsli et al., 2010). This metamorphic age is thus in agreement with a continental subduction event that occurred before the final closure of the southern Neotethys and Arabian–Eurasian collision. $^{40}Ar/^{39}Ar$ dates agree for initial subduction of the Eastern Bitlis massif at 74 Ma followed by

underthrusting of the Pütürge massif under blueschists conditions at 71 Ma (Rolland et al., 2012).

For a compilation of works about the ophiolites of the Lesser Caucasus, the reader is referred to Galoyan et al. (2007, 2009), Rolland et al. (2009b, 2010), Sosson et al. (2010) and Hässig et al. (2013). These authors have shown the following geochemical affinities in the ophiolite-related nappes: (1) the basalts and gabbros mainly bear an enriched tholeiitic composition, contaminated by subduction components, (2) above these series, a layer of alkaline basalt lava flows with large pillows is supposed to represent Ocean Island Basalts (OIB) erupted in seamounts or oceanic plateau(s), and (3) locally some arc-related basalts have been described. In Armenia, the oceanic gabbros of the tholeiitic series were dated to 170–150 Ma similar to radiolarian ages (Danelian et al., 2010), while the alkaline series were dated at c. 117 Ma (Rolland et al., 2009b).

1.2.2 Northeast Anatolia

The East Anatolian Platform (EAP) represents a continental platform between the northern and southern branches of Neotethys (Bozkurt and Mittwede, 2001). As for the SAB, the EAP represents a sliver of continental crust having rifted off northern Gondwana, which drifted to the north, which resulted into collision with Eurasia (Adamia et al., 1977; Biju-Duval et al., 1977; Dercourt et al., 1986; Şengün, 2006; Stöcklin, 1974; Stöcklin & Bhattarai, 1977).

The Eastern Pontides are interpreted as a part of the Sakarya Zone (Okay & Şahintürk, 1997). It represents an active continental margin of Eurasia, which was formed as a result of northward subduction of Neotethys during Late Cretaceous (Akıncı, 1984; Okay & Şahintürk, 1997; Şengör and Yılmaz, 1981). There is no consensus concerning onset age of subduction, since Jurassic (Adamia et al., 1981; Hess et al., 1995; Nikishin et al., 2003; Topuz et al., 2013b), Cenomanian–Turonian (Okay & Şahintürk, 1997; Yılmaz et al., 1997) or Albian (Okay et al., 2006) ages have been proposed. The lack of consensus equally stands when considering the end of subduction and the onset of continental collision; as proposed range stretches out from the end of Eocene (Peccerillio & Taylor, 1976; Robinson et al., 1995; Şengör & Yılmaz, 1981), to the Middle Eocene (Yılmaz et al., 1997) and even the Paleocene (Okay & Şahintürk, 1997).

Figure 36 - Structural map of the Lesser Caucasus-Eastern Pontides-Northeast Anatolides regions. Turkish zone modified from the 1:1 250 000 geological map of Turkey (MTA 2011); the Georgian-Armenian zone of the Caucasus after Sosson et al. (2010); the Iranian zone from Mederer (2013).

The NE Anatolian ophiolites have been studied to characterize their geodynamic environments (Eyüboğlu et al., 2007; Parlak et al., 2013; Rice et al., 2006; Sarifakioğlu et al., 2009; Topuz et al., 2013b; Yılmaz et al., 2010). Geochemical analyses of these ophiolites show similar rock types as in Armenia as well as most of the ophiolites worldwide, that is to say Mid Ocean Ridge Basalt (MORB) to volcanic arc rocks and Within-Plate Basalts (WPB). Lateral continuity between NE Anaolia and Armenia through the comparison of lithostratigraphic colons illustrates similar successions and relations as those well identified in the Lesser Caucasus, especially the timing of the emplacement of tectonic thrusts and related sedimentary deposits. Our field investigations to the north of the Erzincan basin has also shed light on an outcrop of low-grade metamorphic rocks of volcanic origin overthrusted by the ophiolites towards the south on the northern side of the Erzincan basin, along the North Anatolian Fault (NAF) and Northeast Anatolian Fault (NEAF) (**Figure 37**).

B: Geological cross-section illustrating the positioning and structural relationships between the main units based on field observations.

1.3 Structural Continuity

In order to highlight the main structural, geochemical and temporal evidences toward structural continuity between the Lesser Caucasus and NE Anatolia we present new data pertaining to the ophiolites and potential sole lithologies of these bodies, as well as published data used to complete our data set.

1.3.1 Lithostratigraphic sections

In this paper we overview the lithostratigraphic sections compiled from Bergougnan (1987), Bozkuş (1998), Bozkurt & Mittwede (2001), Gedik (2008), Moix et al. (2008), Özgül & Turşucu (1984), Okay & Tüysüz (1999) and Sokolov (1977) for the Turkish and Armenian domains and their implications for the geological evolution of that region. These data are completed by investigations carried out during a field campaign in 2011 (**Figure 38**). This input from pervious works offers a series of well-constrained data on the ophiolites, with precise and modern dating of the magmatic and metamorphic events. Structural/paleogeographic units are linked to one another in order to precise their lateral continuation. Integrated in a larger tectonic framework we use these lithostratigraphic sections to constrain the origin of the NE Anatolian ophiolite nappe as a portion a greater nappe, including the Lesser Caucasus ophiolites.

In the Lesser Caucasus, all ophiolite outcrops feature three main superposed lithotectonic units (Galoyan, 2008; Hässig et al., 2013; Rolland et al., 2009a; 2009b; 2010; Sosson et al., 2010). An upper unit with serpentinite, gabbro, pillow lava and volcanic rocks with interlayered reefal limestone is ascribed to the ophiolite. A Coniacian–Santonian detrital deposit, reworking elements from the entire ophiolitic unit is also included in this unit. Below the ophiolite unit is a tectonic melange including rock types ranging from low grade (greenschist facies) meta-basalts, meta-cherts, metamorphosed serpentinites, lenses of ophiolites, garnet bearing amphibolites and/or alkali basalts. The lower unit comprises basalts, overlain by Lower Cretaceous (Valanginian–Barremian) limestones, which are in turn unconformably covered by Late Paleocene flysch to Lower Eocene limestone as well as Middle to Upper Eocene volcanogenic deposits.

In NE Anatolia, the TAP is made up of a succession of thrust sheets (Okay, 2008). The topmost thrust sheet is made up of ophiolite and/or ophiolitic melange forming large isolated bodies (e.g. Gutnic et al. 1979; Özgül 1984; Özgül & Turşucu, 1984). The thrusting occurred in the Late Cretaceous, in the Eocene and in the Early Miocene. The obduction of preserved ophiolite was associated with subduction and high pressure metamorphism of the northern margin of the TAP. The more distal portions of the obducted ophiolite were emplaced over the Cretaceous sedimentary rocks.

The continental collision during the late Palaeocene-Early Eocene between the TAP and the Eastern Pontides led to a second phase of convergence by folding and thrusting.

1.3.2 Geochemical analyses

Samples from the Lesser Caucasus and NE Anatolian ophiolites and related metamorphics were analyzed for major elements, trace and Rare Earth Elements (REE; **Table 11**). Samples were analyzed at the C.R.P.G. (Nancy, France). ICP-MS analytical procedures and analyses of standards for can be found on the following website (http://www.crpg.cnrs-nancy.fr/SARM).

The sampling was undertaken during a field campaign in 2011. Additional data pertaining to the other Armenian ophiolites along with the Turkish ophiolites are published in Galoyan (2008), Hässig et al. (2013), Parlak et al. (2013) and Rolland et al. (2009a; 2009b; 2010). In order to designate rock groups, trends and tectonic environments (Floyd & Winchester, 1975, 1978; Pearce, 1982, 1983, 1996; Peace & Cann, 1973; Pearce & Norry, 1979) relatively immobile elements, such as Ti, Zr, Y, Nb, Ta, Th, V and REEs, were chosen since the immobility of these elements during low grade submarine alteration has been constrained in a number of studies (e.g., Hart et al., 1974; Humpris et al., 1978). We analyzed three types of rocks: (1) gabbro (**Figures 39 A1**; **A2**; **A3**) and (2) basalt (**Figure 39 B1**; **B2**; **B3**) from the ophiolite unit, as well as (3) metamorphic rocks (mainly amphibolites but also greenschist) (**Figure 39 C1**; **C2**; **C3**) from the metamorphic rocks.

Figure 39 - Diagrams for crustal rocks of the ophiolites. Data concerning Erzincan–Erzurum region (Refahiye, Şahvelet and Karadağ) are from Parlak et al. (2013) and this study. Data concerning Amasia, Stepanavan, Sevan and Vedi are from Hässig et al. (2013), Galoyan et al. (2007, 2009) and Rolland et al. (2009, 2010). A1, B1, C1: Ti/Y vs. Nb/Y discrimination diagram (after Pearce, 1982). A2, B2, C2: Zr/Ti vs. Nb/Y classification diagram (after Pearce, 1996). A3, B3, C3: Ta/Yb vs. Th/Yb tectonic emplacement diagram (after Pearce, 1982).

A tholeiitic (MORB-type) affiliation is found in samples, some with variable enrichment in Large Ion Lithophile Elements (LILE). In Ti/Y vs. Nb/Y and Zr/Ti vs. Nb/Y diagrams these samples plot as basaltic tholeiites. The trace element patterns show generally marked negative anomalies in Ta–Nb and enrichment in Large Ion Lithophile Elements (LILE) (**Figure 40**). The gabbros have rather flat spectra. This variable enrichment is interpreted as a contamination of a depleted mantle source by a subduction component. The association of serpentinites, gabbros, plagiogranites and basalts is typical of ophiolite assemblages, suggestive of an oceanic crust. Therefore, ophiolite rocks, as ophiolite mélange rocks, probably represent supra-subduction back- or fore-arc basins. The second tendency observed is formed by rocks with an alkaline basalt composition.

The metamorphic rocks have a very similar composition to that of alkaline basalts either plotting in Ti/Y vs. Nb/Y and Zr/Ti vs. Nb/Y diagrams as alkaline or transitional rocks. Spidergrams show neat enrichments in LILE, LREE, Ti and Pb for these samples, with no Nb–Ta negative anomalies in respect to LREE enrichment (**Figure 40**). The sub-ophiolitic metamorphic rocks also displays similar patterns as alkaline basalts in spider diagrams. The basalt MORB-normalized spider-diagrams are consistent with an Ocean Island Basalt (OIB) signature, characterized by lack of Nb and Ta negative anomalies and general enrichment in incompatible elements. As quoted by Galoyan (2008) and Galoyan et al. (2009), we interpret these features as representing an OIB signature.

Similar trends have been described by Eyüboğlu et al. (2007) and Sarıfakıoğlu et al. (2008; 2009; 2010). The likeness of these data sets strongly enforces the parallel between NE Anatolia and the Lesser Caucasus and argues that the ophiolites originate from a common supra-subduction oceanic domain.

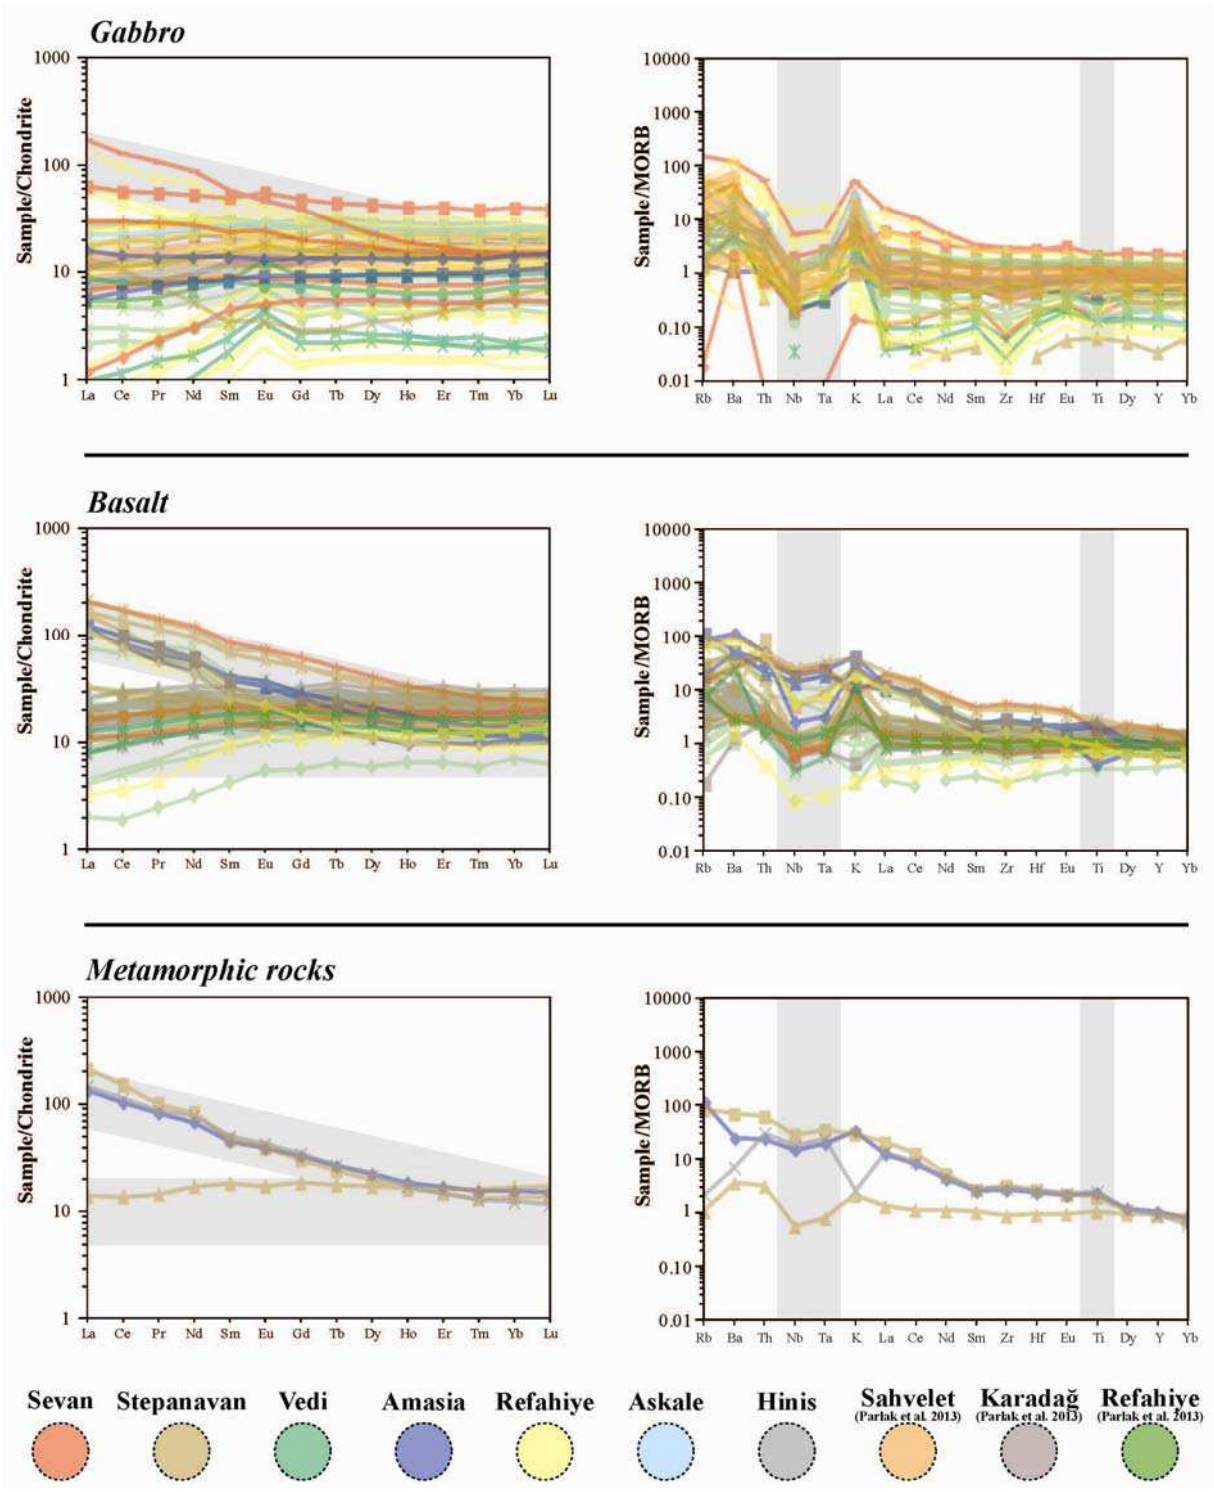

Figure 40 - Chondrite normalized REE spider diagrams and N-MORB normalized multi-element spider diagrams. Data concerning Erzincan–Erzurum region (Refahiye, Şahvelet and Karadağ) from Parlak et al. (2013) and concerning Stepanavan, Sevan and Vedi from Galoyan et al. (2007, 2009) and Rolland et al. (2009b, 2010). Normalizing values are from Sun and McDonough (1989).

1.3.3 Datings

Ophiolite gabbro containing amphiboles, hydrated during hydrothermal circulation throughout rifting commonly occurs in ophiolite mélange units and massif gabbro outcrops of both NE Anatolia and Lesser Caucasus, and are of particular interest because they may provide constraints on the timing of oceanic accretion and/or of further ophiolite obduction. Similarly, palaeontological dating of the sedimentary cover of ophiolites (i.e. radiolarites) provide minimum age constraint on the timing of ocean opening (Bill et al., 2001; Chiari et al., 1997, 2000; Danelian et al., 2000; De Wever et al., 1987; Göncüoğlu et al., 2006). Published geochronological data from ophiolite rocks of the İzmir-Ankara-Erzincan and Sevan-Akera suggest Middle to Upper Jurassic ages. Cretaceous ages are generally obtained from the metamorphic sole rocks (e.g. Harris et al., 1994; Önen, 2003) suggesting emplacement throughout these times.

These data (**Figure 41**) are suggestive of the formation of a continuous oceanic domain between the TAP and SAB to the south and the Pontides and Somkheto-Karabagh arc to the north. These ages also indicate emplacement due to a common obduction event.

1.4 Discussion and Geodynamic implications

The emplacement of NE Anatolia and Lesser Caucasus ophiolites, now linked together, over the passive continental margin to the south requires at least 60 km tectonic transport from the northern Neotethyan suture to their emplacement in their current position, 60 km from Sevan–Akera suture to Vedi for the Lesser Caucasus and at least 80 km from Ankara-Erzurum suture to Hınıs for NE Anatolia. In all these areas the obducted ophiolite sequences display supra-subduction affinities. The geochemical composition of the amphibolites in the metamorphic units beneath the Stepanavan, Amasia and Hınıs ophiolites shows a distinct alkaline affinity similar to the alkaline oceanic island basalts (OIB) suite ascribed to magmatic processes prior to obduction and so part of the ophiolites in Armenia (Vedi, Stepanavan and Amasia) (Galoyan et al., 2007, 2009; Galoyan, 2008; Rolland et al., 2009b, 2010; Sosson et al., 2010).

The alkaline rocks in both regions (NE Anatolia and Lesser Caucasus) are not related to the generation of the SSZ type oceanic crust. We consider these alkaline rocks, found directly on the ophiolite body in Armenia, outcropping as preserved metric pillow lavas as markers of an ocean environment at the time of alkaline volcanism dated c. 117 Ma (mid-Early Cretaceous) by Rolland et al. (2009b). Consequently, the alkaline lithologies are regarded as formations emplaced on the oceanic crust prior to the obduction event, thus, typical of the ophiolite series of this area.

When considering an intra-oceanic subduction model for the origin of slow spreading ophiolites, observations lead to conclude that the volcanic arc is missing. The only evidence of any remains of such a volcanic arc structure can be found in the ophiolitic sole lithologies evidenced by geochemical tendencies. Determining whether ophiolites are of fore- or back-arc origin is not simple because of intricate obduction initiation as well as syn- and post-obduction processes. Both scenarios, fore- or back-arc origin, suggest the existence of an

intra-oceanic arc. The structural and geochemical processes leading to their formation are almost identical, except for less important subduction contamination for back-arc tholeiites.

It has been suggested that the Karadağ ophiolites are representative of a fore-arc environment due to boninitic chemical signatures (Crawford, 1989; Falloon & Crawford, 1991), typical of SSZ magmatism (Parlak et al., 2013). In this scenario the arc would then be either accreted to the Pontides margin (to the north) or subducted under it. There is no evidence of this arc to the north of the ophiolites, except for U-Pb ages which are ascribe to a continuous activity along the southern margin of Eurasia (Rolland et al., 2011; Ustaömer et al., 2012). The only arc is the Pontides and Somkheto-Karabakh, which are limited to the south by the north dipping subduction of ophiolites evidenced by eclogite facies metamorphism (Topuz et al., 2013b) in the Refahiye area.

However, more recent investigations have shown that boninites are not solely found in fore-arc but also in back-arc environments (Deschamps & Lallamend, 2003; Falloon et al., 1992; Teklay, 2006). In addition, Deschamps & Lallemand (2003) tends to ascribe boninites more to a back-arc environment. Furthermore, observations made by Rice et al. (2009) state that the Karadağ ophiolites show proof of the presence of an intra-oceanic arc. The ages found for this formation are Upper Cretaceous but the authors also remarked by Rice et al. (2009) that *"As no plutonic bodies were observed, it is inferred that only the upper part of the arc is preserved, possibly because the lower part of the arc was detached and subducted."* It is then arguable that the older part of the arc, older than Upper Cretaceous, has disappeared through a continent-arc accretion/subduction process as described in Boutelier et al. (2003) and Shemenda (1994), or Ellis et al. (1999).

The mélanges found under the ophiolitic units represent, in part, dismembered pieces of the thrusted ophiolites which fell in front of the obduction front throughout obduction (Festa et al., 2010; Huene et al., 2004; Vannucchi et al., 2008), as well as scraped off features of the underthrusted unit (Cloos & Shreve, 1988; Dilek & Whitney, 1997; Elitok & Drüppel, 2008). This lithologic blend was then overthrusted by the ophiolitic body during emplacement and incorporated and metamorphosed throughout thrusting with other metamorphics beneath the ophiolites (Engi et al., 2001).

In the Erzincan area bibliographic sources as well as field observations evidence the presence of a dismembered thrust sheet of meta-carbonate rock containing Permian foraminifers (Özgül, 1981) topping highly schistosed metamorphosed magmatic rocks, directly under the obduction contact. These marbles could represent mega-lenses emplaced

through tectonic transport due to differential movements between over-thrusted upper ophiolite unit and under-thrusted Tauride Anatolide Platform unit (TAP) or mega-olistolites. This interpretation only leads us to say that the foraminifers evidence that an oceanic domain existed during the Permian between the northern passive margin of the TAP and the area where the future ophiolite will be generated or formed, thus the existence of Neotethys during the Permian.

As for the metamorphic rocks, they may have originally been emplaced anywhere between the passive continental margin (to the south) and the future obducted ophiolite (to the north).We ascribe their schistosity to the intense shearing endured by these rocks throughout ophiolite emplacement. The basal contact of this unit being shielded by Cenozoic deposits of the Erzincan Basin renders it difficult to affirm that these rocks were originally located on the passive (continental or oceanic) margin. This includes a fore- or back-arc environment which is now only testified by sub-ophiolitic metamorphics caught between the underthrusted continent and overthrusted ophiolites. Analyses of these Erzincan metamorphic rocks, phyllite with calc-alkaline affinities, are documented by Gücer et al. (2007). Their geochemistry testifies of meta-basalts with tholeiitic as well as calc-alkaline tendencies. Even if there is no geochronologic data to bracket the original emplacement of these rock types before obduction, the presence of these rocks argues the occurrence of a volcanic arc between the passive continental margin to the south and the future ophiolites to the north, prior to obduction. This further argues an intra-oceanic subduction which accounts for the creation of oceanic crust in a supra-subduction setting.

The geochemical affinities and corresponding protoliths determined for all of these metamorphic rocks are compatible with a volcanic arc environment (Gücer & Aslan, 2009). Also recent $^{40}Ar/^{39}Ar$ ages have been calculated by Aslan et al. (2011) for plagioclases populations which yield ages of 94.1±3.3 Ma and 60.7±4.9 Ma for the metamorphism of this unit. Let us point out that these ages are similar to those of Stepanavan metamorphic unit (95-91 Ma and 71 Ma; Rolland et al., 2009a).

The field relations are thus compatible with a model of obduction of a back-arc domain with oceanic crust slicing after OIB emplacement, which explains why we find alkaline rocks both underneath and on top of the ophiolite. The alkaline outcrops would have been under-thrusted as the ophiolite underwent an intra-oceanic scaling process. Two hypotheses can account for the absence of the expected intra-oceanic island arc: (1) the progressive slicing and alteration by tectonic erosion of the volcanic arc during the obduction or (2) a subduction

"jump" behind the fore-arc block, dragging the volcanic arc with it as proposed by Shemenda (1994). This latter model is suggested by some volcanic blocks in the Stepanavan blueschists and by the paleo-arc complex overprinted by low grade metamorphism found under the obducted ophiolite sequence to the north of the Erzincan basin. In central and eastern Turkey, remnants for such intra-oceanic subduction have also been documented between 169.91+/- 0.8 and 177.08 +/- 0.96 Ma (Çelik et al., 2011).

From all the available geological data, we propose the following model for the evolution of the NE Anatolian and Lesser Caucasus regions (**Figure 42**):

1- The magmatic and metamorphic rocks of all the ophiolites have similar geochemical compositions. The ophiolitic rocks are all of similar age (between 150 and 170 Ma; Çelik et al., 2011; 2013; Galoyan et al., 2009; Rolland et al., 2009a, 2009b; Sosson et al., 2010; Topuz et al., 2013a, 2013b).

2- The two magmatic suites were emplaced one on top of the other: a gabbroic basement of supposedly back-arc oceanic crust topped by thick basaltic flows with an alkaline tendency. This confirms the hypothesis of a single ophiolitic nappe (Galoyan, 2008) over the SAB topped by a volcanic series of hot-spot type, dated c. 117 Ma in Rolland et al. (2009b).

3- The ages of the syn-tectonic sedimentary deposits limit the beginning of obduction of this oceanic domain to Coniacian–Santonian times. Datings on the flysch at Sevan and Vedi indicate similar dates as well as those found in the literature for the NE Anatolian domain (Dilek & Thy, 2006; Okay, 2008). This is compatible with the context of the closure of Neotethys.

4- This new contribution in the comprehension of the geodynamic evolution of NE Anatolia and the Lesser Caucasus supports the presence of two north dipping subduction zones: (1) a subduction under the Eurasian margin and (2) farther south, an intra-oceanic subduction allowing the continental domain to subduct under the oceanic lithosphere, thus leading to ophiolite emplacement. This extends recent geodynamic models for the Lesser Caucasus (Hässig et al., 2013; Rolland et al., 2010; Sosson et al., 2010) eastwards to include NE Anatolia.

5- The missing of the volcanic arc formed above the intra-plate subduction may be explained by its dragging under the obducting ophiolite with scaling by faulting and tectonic erosion. It is hypothesized that the part of the blueschists of Stepanavan corresponds to this missing volcanic arc (Galoyan et al., 2007; Rolland et al., 2009a). In the Erzincan region geochemical traces (Parlak et al., 2013) and field observations lead to the confirmation of this

hypothesis because of the presence of low-grade metamorphic rocks of volcanic origin that are found under the ophiolitic rocks obducted from north to south along the northern edge of the Erzincan basin.

Figure 42 - Middle Toarcian (c. 180 Ma) to present day palaeotectonic evolution of the NE Anatolian-Lesser Caucasus region. Maps modified from Middle East Basins Evolution Programme palaeotctonic maps of the Middle East (Barrier and Vrielynck, 2008) illustrating our new interpretation.

When considering the discontinuous occurrences of metamorphic rocks with calc-alkaline tendencies along the northern Neotethyan suture, we do not see the problem with punctual occurrences of arc volcanism due to the intra-oceanic subduction, as opposed to a continuous uninterrupted volcanic arc.

IV.1 Article 4 – Multi-stage metamorphism in the South Armenian Block during the Late Jurassic to Early Cretaceous: tectonics over south-dipping subduction of Northern branch of Neotethys

Afin de mieux déterminer les modalités de mise en place des ophiolites dans le Petit Caucase, nous nous sommes intéressés au socle cristallin du bloc sud arménien (SABCB). C'est sur ce domaine que les ophiolites arméniennes se sont mises en place dans le Petit Caucase. Cette étude fournit ainsi des informations clés et sans précédent concernant la fermeture du domaine océanique téthysien au nord de la plate-forme SAB-TAP. Le SABCB a une histoire géologique complexe et mal contrainte comprenant :

(1) un métamorphisme présumé panafricain de haut dégré (Baghdasarian *&* Ghoukasian, 1983; Aghamalyan *et al.*, 2011a; 2011b),

(2) une phase de rifting conduisant à l'ouverture de l'océan Néotéthys ainsi qu'à la dérive à partir de Gondwana au cours du Permien jusqu'au début du Mésozoïque (Sosson *et al.*, 2010 *et les références qui y sont citées*),

(3) l'obduction de croûte océanique dans le milieu du Crétacé supérieur (Galoyan *et al.*, 2009; Rolland *et al.*, 2009b),

(4) suivie par la fermeture totale du domaine océanique et la subduction continental/collision à la fin du Crétacé (Rolland *et al.*, 2009a; 2011; Sosson *et al.*, 2010).

Le SABCB affleure uniquement dans une étroite fenêtre tectonique au nord-ouest de Erevan, dans le massif de Tsaghkuniats près du village de Bjni (Belov *&* Sokolov, 1973; Aghamalyan, 1978; 1998; Shengelia *et al.*, 2006). Pour obtenir des limites temporelles concernant l'enchaînement ainsi que la durée des événements géologiques affectant cette zone, nous avons mené une étude structurale, pétrologique et géochronologique de ce massif.

Dans le massif de Tsaghkuniats le socle cristallin est constitué de gneiss granitiques (orthogneiss) et de micaschistes paradérivés intrudés par des granodiorites et leucogranites. Ceux-ci sont recouverts en discordance par une série sédimentaire datée du Crétacé supérieur au Paléocène composée de conglomérats remaniant des roches ophiolitiques, des grès ainsi que de marnes. Ces formations sont à leur tour recouvertes en discordance par des sédiments volcanogéniques de l'Eocène moyen-supérieur et des basaltes du Plio-Quaternaire au Présent.

Nous présentons de nouvelles datations (U-Pb et $^{40}Ar/^{39}Ar$) concernant la mise en place d'un corps granodioritique et son encaissant métamorphique. Le métamorphisme régional est interprété comme témoin :

(1) des conditions d'enfouissement et d'épaississement dans un gradient régional barrovien MP-MT (staurotide-disthène, M1) à c. 160-157 Ma, avec la mise en place de magmas dioritiques à c. 156-150 Ma,

(2) d'une décompression adiabatique caractéristique de fusion partielle et de production de leucogranites à c. 153 Ma, suivie par des conditions HT-BP (andalousite-K-feldspath, M2),

(3) d'une phase de cisaillement et de recristallisation attribuées à un bombement au c. 130-150 Ma et à un refroidissement à 400°C à c. 123 Ma (M3).

Nous montrons, pour la première fois, une évolution métamorphique polyphasée étonnamment jeune pour cette région préservée dans le SABCB. Nous ne notons pas dans les âges obtenus d'héritage panafricain comme il avait été suggéré par les datations Rb-Sr précédentes (Shengelia *et al.*, 2006). Cette évolution métamorphique, le magmatisme calco-alcalin qui lui est associée et les marqueurs cinématiques sont interprétés comme les témoins d'une subduction plongeant vers le sud, sous le SAB.

Ces résultats et interprétations sont intégrés dans un modèle illustrant l'évolution géodynamique de la marge nord du SAB. Que cette zone de subduction se prolonge plus à l'ouest reste à être prouvé, car les affleurements de socle cristallin en NE Anatolie et/ou sur la TAP sont rares. Nous avons cependant pu observer une forte empreinte métamorphique thermique accompagnée d'intrusifs granitiques sous la nappe ophiolitique non métamorphique dans les Taurides au SE d'Erzurum, mais nous n'avons pas encore pu ni étudier en détail cette zone, ni obtenir d'âge préliminaire.

Cette étude a fait l'objet d'une publication en révision dans le *Journal of Asian Earth Sciences*.

Multi-stage metamorphism in the South Armenian Block during the Late Jurassic to Early Cretaceous: tectonics over south-dipping subduction of Northern branch of Neotethys

Abstract

The geologic evolution of the South Armenian Block (SAB) in the Mesozoic is reconstructed from a structural, metamorphic, and geochronologic study including U-Pb and $^{40}Ar/^{39}Ar$ dating. The South Armenian Block Crystalline Basement (SABCB) outcrops solely in a narrow tectonic window, NW of Yerevan. The study of this zone provides key and unprecedented information concerning closing of the Tethys oceanic domain north of the Taurides-Anatolides platform from Middle Jurassic to Early Cretaceous times. The basement comprises of presumed Proterozoic orthogneiss overlain by metamorphosed pelites as well as intrusions of granodiorite and leucogranite. During the Late Jurassic and Early Cretaceous times structural, geochronological and petrological observations show a multiphased evolution of the northern margin of the SAB. A south-dipping subduction under the EAP-SAB is proposed in order to suit recent findings pertaining emplacement of relatively hot subduction related granodiorite as well as the metamorphic evolution of the crystalline basement in the Lesser Caucasus area.The metamorphism is interpreted as evidencing: (1) M1 Barrovian MP-MT conditions (staurolite-kyanite) at c. 157-160 Ma and intrusion of dioritic magmas at c. 150-156 Ma, (2) near-adiabatic decompression is featured by partial melting and production of leucogranites at c. 153 Ma, followed by M2 HT-BP conditions (andalusite-K-feldspar). A phase of shearing and recrystallization is ascribed to doming at c. 130-150 Ma and cooling at 400°C by c. 123 Ma (M3). Structural observations show (1) top to the north shearing during M1 and (2) radial extension during M2. The extensional event ends by emplacement of a thick detrital series along radial S, E and W-dipping normal faults. Further, the crystalline basement is unconformably covered by Upper Cretaceous-Paleocene series dated by nannofossils, evolving from Maastrichtian marly sandstones to Paleocene limestones.

1.1 Introduction

The Crystalline Basement of the South Armenian Block (SAB) (**Figures 43A** & **B**) has a geological history poorly constrained. The SAB was involved in a long and complex tectonic evolution including (1) presumed Panafrican high-grade metamorphism (Baghdasarian and Ghukasian, 1983, Aghamalyan et al., 2011a; 2011b). However, contrary to other occurrences of Paleozoic sedimentary rocks SE of Yerevan (Sosson et al., 2010), the presumed Paleozoic sediments of the Tsaghkuniats crystalline massif are metamorphosed. Both the metamorphic basement and cross-cutting intrusions are unconformably covered by Upper Cretaceous deposits (**Figures 44A**, **B** & **C**). This observation leads us to question the Precambrian age forwarded for metamorphism, as well as the tectonic setting and its geodynamic cause. Indeed, several geodynamic processes can explain the metamorphic history of this basement, including (2) a rifting stage leading to Neotethys ocean opening and drifting from Gondwana in the Permian to Early Mesozoic times (Sosson et al., 2010 and references herein), (3) oceanic closure by subduction of Paleotethys from the Early to late Mesozoic and (4) subsequent continental subduction/ocean crust obduction in the middle-Late Cretaceous (Galoyan et al., 2009; Rolland et al., 2009b), followed by (5) continental collision or accretion to the Eurasian margin in Late Mesozoic/Early Cenozoic times (Sosson et al., 2010) and depending on authors the Arabia-Eurasia collision from middle to late Eocene up to Oligocene (Hempton, 1985; Robertson et al., 2012; Rolland et al., 2009a; 2012; Yılmaz, 1993). Moreover, the influence of the Cimmerian orogeny, known more eastward in Iran, is also a possible cause of this metamorphism. Consequently, the SAB Crystalline Basement (SABCB) needs to be investigated by detailed geochronological and petro-metamorphic (P-T-t) studies to evaluate the importance of these post-Paleozoic events in this part of the Caucasus region.

In order to constrain the timing of these geological events, field geology and sampling were undertaken in the SABCB, which outcrops in a narrow tectonic window to the NW of Yerevan, in the Tsaghkuniats massif (Aghamalyan, 1983; **Figures 43B** & **44A**). This study presents new U-Pb and $^{40}Ar/^{39}Ar$ age data to temporally constrain the metamorphism and magmatism of the basement. This study is complemented by a petrologic and Pressure-Temperature (P-T) analysis to interpret the metamorphic significance of these rocks. Subsequently, we propose a tectonic and geodynamic reconstruction of the evolution of the SAB throughout the closing of the northern Neotethys oceanic domain.

1.2 Geological Setting

1.2.1 Origin of the SAB

Palaeomagnetic analyses indicate palaeo-latitudes for the SAB during the Early and Middle Jurassic at least 2000 km farther south than its current position (Bazhenov et al., 1996; Meijers et al., 2013). This argues a Gondwanian origin of the SAB, as also suggested by the dating undergone by Baghdasarian and Ghukasian (1983) and palaeogeoraphic reconstructions (Barrier and Vrielynck, 2008; Knipper and Khain, 1980; Monin and Zonenshain, 1987; Robertson and Mountrakis, 2006; Şengör et al., 1988). The rifting of the Taurides-Anatolides (including the SAB) from Gondwana is documented as initiating during Triassic times (Gealey, 1988; Kazmin, 1991; Mart, 1987).

1.2.2 Post-Paleozoic tectonic events

1.2.3 Tethys subduction – Cimmerian orogeny

Throughout the Mesozoic and Cenozoic, the northern margin of the SAB, as well as the southern Eurasian margin, was involved in subduction and accretion/collision processes resulting in closure of northern branch of the Tethys ocean (Adamia et al., 1981; 2011; Dercourt et al., 1986; Galoyan, 2008; 2009; Golonka 2004; Hässig et al., 2013; 2014; Nikishin et al., 1998; Ricou, 1994; Robertson, 2002; Rolland et al., 2009a; 2009b; 2010; 2011; 2012; Şengör and Yılmaz, 1981; Sosson et al., 2010; Stampfi et al., 2001; Topuz et al., 2013; Yilmaz et al., 2000; Zakariadze et al., 1990; 2005). The north-dipping subduction of the Tethyan oceanic domain under the southern Eurasian margin, from Middle Jurassic to middle-Late Cretaceous times (c. 170-83 Ma), is evidenced in the Pontides and Somkheto-Karabakh regions which exhibit continuous volcanic arc related to subduction throughout this period (Adamia et al., 1981; Yilmaz et al., 2000). Within the northern branch of Neotethys/Paleotethys, a period of intra-oceanic subduction has been evidenced by the presence of obducted ophiolites along the Lesser Caucasus (Adamia et al., 1981; Ahamalyan, 1978; 1998; 2011a; 2011b; Galoyan, 2008; Hässig et al., 2013; Rolland et al., 2009b; Sosson et al., 2010). These bodies of non-metamorphic obducted oceanic crust were formed in a back-arc to supra-subduction zone setting during the Middle Jurassic north of the SAB (Aghamalyan, 1998; Galoyan, 2008; Rolland et al., 2009b, 2011; Hässig et al., 2013). The intra-oceanic subduction zone is most likely north-dipping, as suggested by the overall

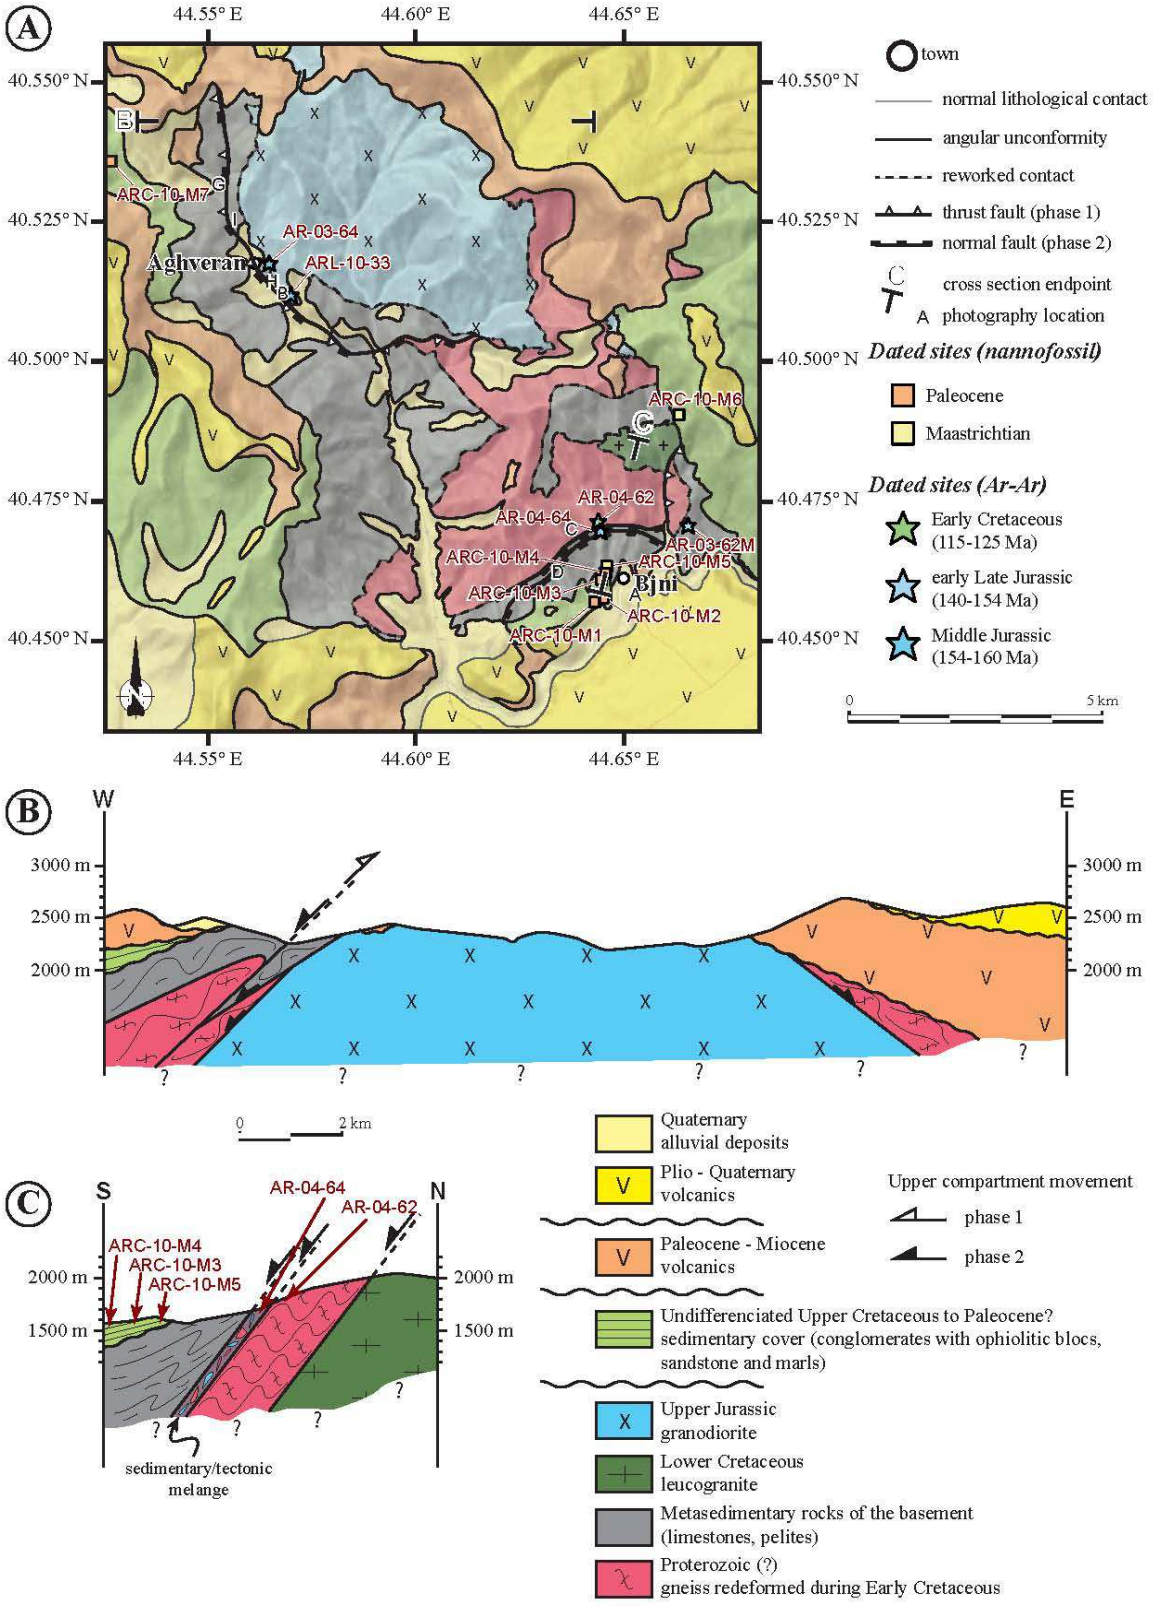

Figure 44 - A, structural map of the Tsaghkuniats massif, modified from Aghamalyan (1983). Location of this map is indicated on figure 43B. Plot of geological sections of Figure 44B and 44C along with localization of dated samples by the U-Pb and $^{40}Ar/^{39}Ar$ methods and paleontological identification. Location of field photographs of Figure 45 indicated as well. B and C, sketch geological cross sections of the Tsaghkuniats massif.

geometry of the tectonic wedge. The outcrops of blueschist and amphibolite facies rocks below the ophiolite nappe along the Sevan-Akera suture zone in the Stepanavan (Rolland et al., 2009a; Sosson et al., 2010) and Amasia areas (Hässig et al., submitted), respectively, also argue for the two north dipping subduction zones. These two northward dipping subduction zones (below the southern Eurasian margin and intra-oceanic between the southern Eurasian margin to the SAB) are considered to be synchronous, as evidenced by the timing of peak metamorphism (c. 95-91 Ma and c. 92-88 Ma) for these lithologies encompassed within the period of activity of the Pontides and Somkheto-Karabakh arc.

Recent investigations along the Pontides and Lesser Caucasus sutures have not evidenced any Cimmerian tectonic phase (Topuz et al., 2013; Rolland et al., 2012).

1.2.4 Collisional stages

The collision between the SAB and the southern Eurasian margin started during the Late Cretaceous-Paleocene as evidenced by the formations of a foreland basin in the southeastern part of the belt and by the folding, uplift and erosion of the Sevan–Akera suture zone (Sosson et al., 2010). From Middle Eocene to Miocene times, inherited normal faults of the northern SAB passive margin were reactivated as reverse faults progressively deforming molassic deposits. A fold-and-thrust belt type structure developed until the Miocene through the development and propagation of décollement faults (Sosson et al., 2010).

The south of the SAB (included in the Taurides-Anatolides) is limited from the Arabian platform by the Pütürge and Bitlis massifs marking the Misis-Andırın and Bitlis sutures (Hempton, 1985; Oberhänsli *et al*., 2010; 2014; Rolland et al., 2012). Timing of continental subduction is documented at c. 76-71 Ma (Göncüoğlu and Turhan, 1984; Hempton, 1985; Oberhänsli et al., 2010). As for the later collision between the Taurides-Anatolides and the Arabian platform, timing is still debated with authors proposing ages ranging from middle to late Eocene up to Oligocene (Hempton, 1985; Yılmaz, 1993; Robertson et al., 2012) with complete closure of the southern branch of Neotethys.

1.2.5 Metamorphism and magmatism in the SAB crystalline basement

The SABCB only outcrops in a 600 km² zone NE of Yerevan, the Tsagkhuniats massif (Aghamalyan, 1978; 1998; Belov and Sokolov, 1973; Shengelia et al., 2006). This massif

features metamorphic rocks characterized by gneisses, micaschists along with granodiorite and leucogranite intrusions (Sosson et al., 2010). It is discordantly overlain by an Upper Cretaceous to Paleocene sedimentary cover (**Table 12**; **Figures 44A**, **44C** and **45A**) comprising of conglomerats reworking ophiolitic rocks, sandstone and marls. These sediments are in turn unconformably overlain by Paleocene to Miocene volcanics and covered by discordant Plio-Quaternary volcanites present throughout the region (**Figure 44A**). Previous studies of the Tsaghkuniats massif rocks have evidenced a high-grade regional metamorphism (Aghamalyan et al., 1978; Shengelia et al., 2006) of the magmatic-derived basement, intercalated with mafic and sedimentary rocks. According to prior petrological and geochemical results, the mafic rocks are of amphibolites facies (Aghamalyan et al., 1978; 2011a). P and T conditions range between T = 420~640°C and P = 1.6~5.7 kbar, which argues for a geothermal gradient between 25 and 50 °C/km (Aghamalyan et al., 2011b).

Presumed origin of the SABCB dates back to the Proterozoic as is suggested by an age of 610 ± 36 Ma obtained by Baghdasarian and Ghukasian (1983). This age was acquired using the Rb-Sr isochron method on the Bjni migmatite-granitic massif of the Tsaghkuniats crystalline outcrop (**Figure 44A**). This age tends to supports that the SABCB is of Gondwanian origin, as suggested by Knipper and Khain (1980), Monin and Zonenshain (1987), Robertson and Mountrakis (2006), Rolland et al. (2009b), Şengör et al. (1988), Sosson et al. (2010) and Stampfli and Borel (2002). However, the Rb-Sr method applied to metamorphic rocks is subject to caution and has to be re-evaluated by other methods. Recent field observations allow to evidence structural cross-cutting relations between an undeformed granodiorite intrusion and the metamorphic basement (**Figures 44A** & **B**). U-Pb dating of the granodiorite intrusion would thus provide an upper temporal boundary for the high-grade metamorphism, while the $^{40}Ar/^{39}Ar$ method could be applied to the micaschists from the basement in order to build the P-T path deduced from the metamorphic evolution.

Figure 45 - Representative field photographs of the lithologies of the Tsaghkuniats massif and interpreted structural relationships. 1.3 New Field Observations

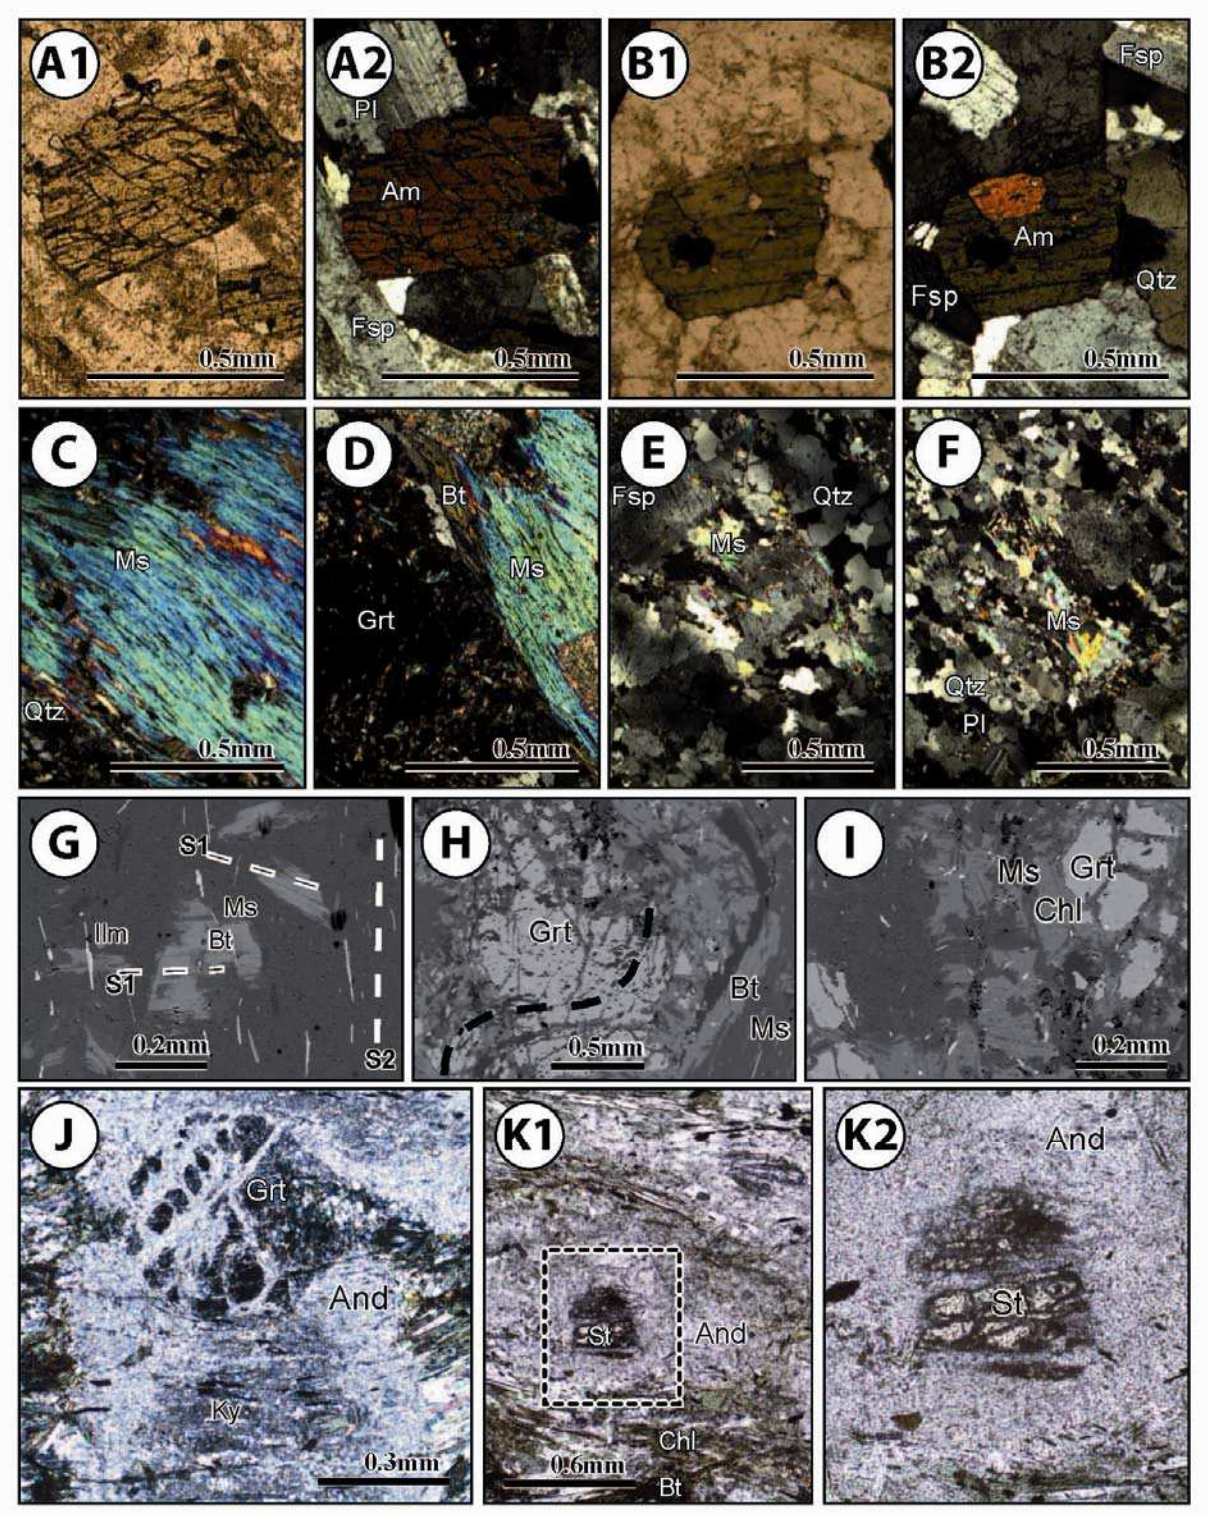
The crystalline basement of the Tsaghkuniats massif is made up of metamorphic rocks characterized by para- and ortho-gneisses with micaschists cross-cut by leucogranite and granodiorite intrusions **(**Baghdasarian and Ghukasian, 1983; Aghamalyan, 1998; Shengelia et al., 2006). A stack of metasedimentary rocks mainly comprised by skarnified limestones is also evidenced. These metasedimentary rocks (**Figures 44A**, **B** & **C**) could belong to the Proterozoic formations (Aghamalyan et al., 1998) or to the Upper Devonian-Permian formations like in the other parts of the SAB, they could also belong to the Upper Devonian-Permian formations (Sosson et al., 2010), but metamorphosed. Normal faults have been observed between the gneiss and the metasedimentary units (**Figures 45C** & **45D**) as well as along a large (≈ 20 km²) outcrop of granodiorite (**Figure 45B**), which appear to be geometrically related to the emplacement of this intrusion. The mineral relationships in the metamorphic rocks (i.e. metamorphic paragenesis, deformation and orientation, as well as cross-cutting relationships; **Figures 45**, **46** & **47**) argue for significant simple-shear deformation of the crystalline basement during a barrovian metamorphic event at high-temperature and mid-to low-pressure conditions.

High-grade micaschists (samples AR-03-62M & AR-04-64) exhibit kyanite-staurolite ± sillimanite -andalusite-K-feldspar-garnet micaschists (**Figures 45F**, **46C**, **D**, **G**, **H**, **I**, **J**, **K1**, **K2**, **47E**, **F1** & **F2**). This mineral assemblage indicates burial of metasediments in the Medium-Pressure and Medium-Temperature (MP-MT) conditions of kyanite-staurolite stability field (550<T<750°C ; P>5 kbar, Johnson and Brown, 2004). Subsequent exhumation in Low-Pressure and High-Temperature (LP-HT) conditions is highlighted by K-feldspar + andalusite assemblage (T<750°C ; P>5 kbar, Soto and Platt, 1999).

Figure 46 - Representative microphotographs of fin sections of rock samples of the Tsaghkuniats massif showing mineral relationships of $^{40}Ar/^{39}Ar$ dated mineral phases. A1 and A2, plane and cross-polarized images, respectively, centered on amphibole of granodiorite sample AR-03-64. B1 and B2, plane and cross-polarized images, respectively, centered on amphibole of granodiorite sample AR-03-64. C, cross-polarized images centered on white mica of micaschist sample AR-03-62M. D, cross-polarized image centered on white mica of micaschist sample AR-03-62M. The white mica molds the garnet and biotite. E, cross-polarized images centered on white mica of leucogranite sample AR-03-64. F, cross-polarized images centered on white mica of leucogranite sample AR-03-64. G, H and I, electron back-scatter (EBS) images of metaschist sample AR-03-64B. J, K1 and K2, optical microscope photography of sample AR-03-62M showing relics of garnet, kyanite and staurolite included in andalusite.



A top-to-north movement is generally observed in the units that are part of the basement rocks. In gneiss outcrops, this deformation is identified by shear-schistosity geometries (C-S; **Figure 45E**), illustrating top-to-north movement. It is represented by nearly north-south trending (N 16°E) shallow southward dipping (18°S) mineral lineation (**Figure 45H**). In a

micaschist outcrop asymmetric pyrite clast were found (**Figures 45I** & **47A**) also showing top-to-north deformation. Pressure-shadow recrystallizations in one oriented sample show a concordant sense of movement with the prior observations that are in agreement with a first stage of syn-metamorphic deformation.

Along the granodiorite intrusion, the localized intense deformation lead to the formation of C and S planes with synthetic C' planes oriented concordantly with general shearing, conform to Choukroune et al. (1987), along a N155°E direction with a west dip (**Figure 45G**). This may also be observed at the mineral scale with the development of shear bands, which distinctly shift well defined and parallelized C and S planes along C' planes (**Figures 45G**, **47B**, **C1**, **C2**, **D1** & **D2**). At the NW boundary of the massif, centimetric scale folding is observed. The fold axes tendency approaches NW-SE orientation (N140°E, 27°W; **Figure 45H**). This deformation is, as for top-to-north deformation, associated with N-S mineral or stretching lineation, illustrating N-S extension, also emphasized by the dome-shape of the massif.

Brittle-ductile deformation is featured by a regional radial-extensional movement around granodiorite and leucogranite intrusions. Normal faults striking through both metasedimentary micaschists and gneiss rocks, along the SW border of the granodiorite outcrop, have strikes varying from NNW in the northwestern part to ESE for the southeastern segments. Dip directions for these faults vary from W to S, as there their strike turns from NNW to ESE, respectively. Normal faults along the SE limit of the leucogranite intrusion present a general strike direction oriented ENE to NNE from W to E, with an overall dip towards the S. In parts of the hanging-wall of these faults are found lower metamorphic grade rocks featured by white mica/biotite schists and phyllades.

We therefore interpret all these brittle ductile structures as related to an extensional event as the result of the massif's exhumation.

Figure 47 - Mineral deformations and associations found in sampled outcrops. A, zoom of Figure 45I of deformed pyrite indicating shear movement in well-foliated metamorphic rock. B, C1, C2, D1 and D2, microphotographs taken with a stereo microscope of shear bands found in micaschist thin sections. B, C1 and D1, are taken in LPNA whereas C2 and D2 are in LPA. E, cross polarized microphotograph of andalusite cross-cutting preexisting white micas. The andalusite features relic kyanite mineral fragments at its core and is molded by biotite. F1 and F2, plane and cross-polarized micrographs, respectively, zoom on andalusite cross-cutting white mica lineation.

1.4 Mineralogy and Pressure-Temperature path of metamorphic rocks

The chemical compositions of minerals were obtained by Electron Microprobe Analysis (EPMA) in order to verify the homogeneity of mineral compositions from core to rim (see **Annexe 8**). A detailed mineralogical analysis of the micaschist (metapelite) sample AR-03-62M (**Table 13**; **Figures 46C**, **D**, **G**, **H**, **I**, **J**, **K1**, **K2**, **47C1**, **C2**, **D1**, **D2**, **E**, **F1** & **F2**) allows us to construct the Pressure-Temperature (PT) path followed by part of the SAB crystalline basement (**Figure 48C**), using the grid established by Holland and Powell (1998) for the KFASH system. The PT path can be described as follows from the main assemblage mineralogy. The co-stability of a Medium P - Medium T (MP-MT) paragenesis defined by (1) staurolite-kyanite-garnet (Alm 0.6)-rutile implies a pressure peak at 7-9 kbar and 500°C < T < 625°C (**Figure 48A**). The breakdown reaction of muscovite + garnet into kyanite + staurolite + quartz (2) implies re-equilibration at 6-7 kbar and 600 ± 50°C. Transformation of kyanite into andalusite, and the crystallization of andalusite + K-feldspar at the expense of muscovite (3) constrain the low P part of the PT path (P < 2 kbar, 600 < T < 650°C), in Low P - High T (LP-HT) condition. This PT evolution is compatible with the occurrence of leucogranites as the PT conditions are almost on the hydrated solidus curve of metapelites.

Rim to rim EPMA analysis of garnet is shown in **Figure 48A**. The garnet is zoned, with a homogeneous central part showing high spessartine (20~24 %) and relatively low grossular (14~16 %) and pyrope (5~7 %) contents. Symmetrical zoning is observed towards higher almandine and, in a lesser extent, pyrope contents towards the rims. The garnet is compositionally zoned in a style that strongly suggests prograde growth zoning during increasing temperature conditions (Spear, 1988; 1993). The garnet profile seems unmodified by post-growth diffusion affecting the rim. Snow-ball inclusion trails are also observed (**Figure 46H**), which is in agreement with garnet rotation and thus growth during shearing. Garnet-Biotite-Plagioclase geothermobarometry provides PT estimates in agreement with low-pressure reequilibration of these minerals, with PT estimates ranging between 360-460°C and 2 ± 1 kbar (**Figure 48B**). Post-temperature peak re-equilibration of biotite is likely as this mineral shows signs of chloritization.

1.5 Geochronology and Geochemistry

1.5.1 Analytical procedures

1.5.1.1 $^{40}Ar/^{39}Ar$ dating

Pure minerals less than 1mm in diameter (between 800µm and 500µm) were obtained using a mortar and pestle and multiple sieving. Datable minerals were separated by careful hand-picking under a binocular microscope to avoid altered grains or inclusions. All samples were irradiated for around 70h (J1) and 10h (J2, J3) in the nuclear reactor at McMaster University in Hamilton (Canada), in position 5c along with Hb3gr hornblende fluence monitor (1073.6 Ma ± 5.30 Ma; Jourdan et al., 2006) and Fish Canyon sanidine monitor (28.03 ± 0.08 Ma; Jourdan and Renne, 2007) for J1 and J2, J3 respectively. The estimated errors of $^{40}Ar^*/^{39}Ar_K$ ratios range between ± 0.1% (2σ), and ± 0.6% (2σ) in the volume where the samples were included.

Samples were analyzed by single-grain CO_2 laser analysis or by furnace step-heating analysis, at the University Nice Sophia Antipolis (Géoazur UMR 7329). Laser analyses were undertaken by step heating with a 50 W CO_2 Synrad 48-5 continuous laser beam. Measurement of isotopic ratios was done with a VG3600 mass spectrometer, equipped with a Daly detector system. Detailed procedures are given in Jourdan et al. (2004). The typical blank values for extraction and purification of the laser system are in the range 4.2-8.75, 1.2-3.9, and 2-6 cc STP for masses 40, 39 and 36, respectively. Furnace analyses were undertaken with a step-heating technique using a double-vacuum high-frequency furnace and a mass spectrometer composed of a 120° M.A.S.E.E. tube, a Baur-Signer GS98 source and a Blazers electron multiplier. Heating lasted 20 min for each temperature step, followed by 5 min for clean-up of the released gas, before introducing the gas into the spectrometer. Ar isotopes were of the order of 100-2000, 100-1000 and 2-200 times the blank for masses 40, 39 and 36, respectively. All measurements were undertaken at the University of Nice (Géoazur UMR 7327). For both $^{40}Ar/^{39}Ar$-dating techniques, the mass-discrimination was monitored by regularly analyzing air pipette volume. Decay constants are those of Steiger and Jäger (1977). The criteria used for defining a plateau age are those described in McDougall and Harrison (1988). Uncertainties on apparent ages, plateau and isochron ages are given at 2σ level, which includes the error on the $^{40}Ar^*/^{39}Ar_k$ ratio of the monitor. For the muscovite datings, the restricted spread in $^{36}Ar/^{40}Ar$ vs. $^{39}Ar/^{40}Ar$ values does not allow the use of inverse isochron method (see **Annexes 9**, **10**, **11**, **12**, **13** and **14**).

1.5.1.2 **U-Pb dating**

LA-ICP-MS U-Th-Pb zircon dating was performed at the University of Montpellier II using a Lambda Physik CompEx 102 excimer laser generating 15 nanoseconds duration pulses of radiation at a wavelength of 193 nm. Approximately thirty zircons were handpicked from the least magnetic concentrates using a binocular microscope, in order to obtain an assortment of the best quality grains. Crystals were then embedded in epoxy resin together with chips of the 91500 standard zircon (Wiedenbeck et al., 1995), grounded and polished to expose their internal structure. For analyses, the laser was coupled to a an Element XR sector field ICP-MS. Laser spot sizes were 50 µm. Samples were ablated under helium in a 15 cm^3, circular shaped cell using an energy density of 15 J/cm² at a frequency of 4 Hz. Analytic signal was acquired during 45 seconds and the blank was measured before each sample during 15 seconds. All isotopes (^{202}Hg, ^{204}Pb+Hg, ^{206}Pb, ^{207}Pb, ^{208}Pb, ^{238}U and ^{232}Th) were measured in pulse counting mode. The isotopes were measured using 15 points per peak and a 20% mass window resulting in 3 measured points for each mass station. Unknowns were bracketed by measurements of the G91500 standard (Wiedenbeck et al., 1995), which were used to calculate a mass bias factor (Pb/Pb ratio) and the inter-element fractionation (U/Pb ratios). The calculated bias factors and their associated errors were then added in quadrature to individual errors measured on each unknown following the procedure described in Horstwood et al. (2003). The decay constants and present-day $^{238}U/^{235}U$ value given by Steiger and Jäger (1977) were used and ages were calculated using the program Isoplot/Ex of Ludwig (2002).

1.5.1.3 **Geochemistry**

The Sr, Pb and Nd isotope analyses were determined using the VG354 5-collector mass spectrometer at the Lyon University following conventional chemical separation at the University Montpellier 2 radiogenic isotope facility. Major and trace element analysis was undertaken at Centre de Recherches Pétrographiques et Géochimiques (CRPG) Nancy (http://www.crpg.cnrs-nancy.fr/SARM/).

Major elements were analyzed on the basis of optical emission spectrum (ICP-OES) using an inductively coupled argon plasma source. The trace elements were obtained using mass spectrometry (ICP-MS), according to the following analytical procedure: solutions are prepared with the addition of $LiBO_2$ and dissolved in HNO_3. The spectrometer inductively coupled to a plasma source (ICP) allows the rapid simultaneous analysis of multiple elements

with great precision. The source is constituted by a flame in which the samples are introduced in aerosol form.

1.5.2 Results

Dating performed on the SABCB has been focused on several lithologies. The same metapelitic sample that was studied for metamorphism (AR-03-62M) was also selected for $^{40}Ar/^{39}Ar$ dating, to perform a PTt path. A basement orthogneiss (AR-04-62) and a leucogranite (AR-04-64) were also analyzed in order to further constrain the thermal history of the study area. Finally, two granodiorite samples were also selected for U-Pb zircon and $^{40}Ar/^{39}Ar$ dating on amphibole, respectively ARL-10-33 and AR-03-64, to fix the pluton emplacement age as well as the early cooling history. $^{40}Ar/^{39}Ar$ and U-Pb dating samples and corresponding age results are found in **Tables 14** and **15**, respectively. Results are shown on **Figures 50** and **51**, compiled in the **Table 16**.

1.5.2.1 Geochronology and geochemistry of the granodiorite pluton

1.5.2.1.1 U–Pb dating

A photography of the dated zircon using a scanning electron microscope is provided in **Figures 50C1**, **C2**, **C3** & **C4**. The zircons show zonation compatible with a magmatic origin. Zircon dating using U-Pb laser ICP-MS ablation of granodiorite sample ARL-10-33 (**Table 14**) yields a concordia age of 150 ± 6 Ma (2σ) (**Figure 50A**) and a Tera-Wasserburg age of 153 ± 2 Ma (2σ) (**Figure 50B**).

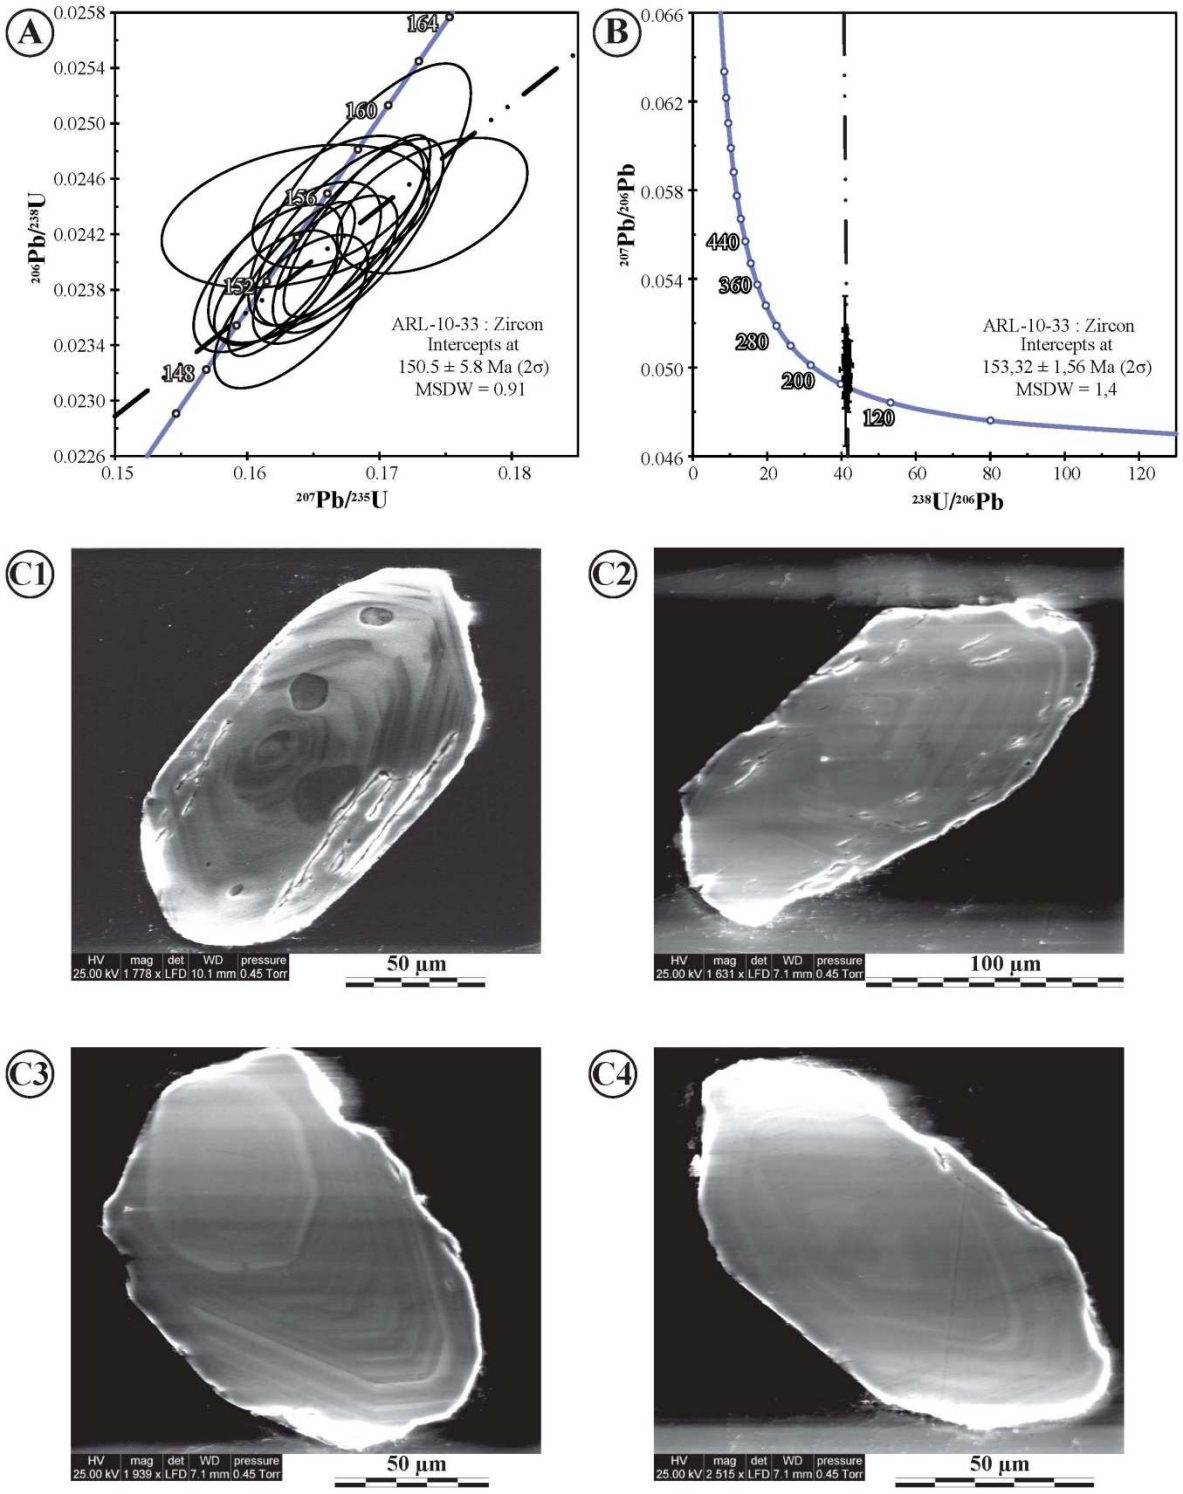

Figure 49 - U-Pb laser ICP-MS ablation concordia, A, and Tera-Wasserburg age diagrams, B, for the samples ARL10-33. C1, C2, C3 and C4 scanning electron microscope photography of dated granodiorite zirons corresponding to numbered analyses of table 14, respectfully. Location of the sample is shown on Figure 45.

1.5.2.1.2 **40Ar/39Ar dating**

The laser dating of the granodiorite sample AR-03-64 amphibole provides a relatively flat $^{40}Ar/^{39}Ar$ spectra with (1) steps 1-2 at 62 Ma representing less than 4% of released ^{39}Ar, (2) a high K/Ca ratio (K/Ca ~ 8) with ages between 147 and 152 Ma representing a total of 41.4% of degassed ^{39}Ar (steps 3-6) and (3) a low K/Ca ratio at high temperatures (K/Ca ~ 1-2) with ages between 157 Ma and 160 Ma representing a total of 54.7% of degassed ^{39}Ar (steps 7-14) (**Figure 51**, **Table 15**). The calculation of the weighted mean age of the spectrum except steps 1-2 gives an age of 156 ± 2 Ma (2σ) with a MSWD of 4.38. The isochron age gives an age of 158 ± 3 Ma (2σ) (MSWD 4.13) and the inverse isochron age is of 157 ± 3 Ma (2σ) (MSWD 4.21), with an intercept $(^{40}Ar/^{36}Ar)_0$ close to air value (266 ± 23). Therefore there is a good agreement between these different age calculations. We ascribe the variation in K/Ca ratio versus cumulative released $^{39}Ar(\%)$ in the high temperature part of the spectrum either to (1) a first phase of amphibole crystallization between 160 Ma and 152 Ma (steps 7-14) and the lower temperature part (steps 3-6) to a second amphibole growth between 152 Ma and 147 Ma, or (2) to recoil effects on the ^{39}K-^{39}Ar reaction in terms of ^{39}Ar distribution. However the two U-Pb and $^{40}Ar/^{39}Ar$ age provide within-error overlapping, which suggests sub-synchronous crystallization of amphibole and zircon at c. 153 Ma.

1.5.2.1.3 **Geochemistry**

The geochemical analysis of granodiorite sample ARL-10-33 (**Table 17**) was done in order to constrain its related geodynamic context. The result shows significant enrichments in Large Ion Lithophile Elements (LILE) and in Light Rare Earth Elements (LREE) as compared to Heavy Rare Earth Elements (HREE). The chondrite-normalized patterns have $(La/Sm)_N$ of 4.9 and $(La/Yb)_N$ ratios of 23.2. A well-marked negative Nb-Ta anomaly is observed and may be accounted by contribution of a subduction (or crustal) component in the source (Jacobsen and Wasserburg, 1980; **Figure 49**; **Table 17**).

Radiogenic isotopic analysis shows (1) $^{87}Sr/^{86}Sr_{(i)}$ value of 0.70341, (2) a $^{144}Nd/^{144}Nd_{(i)}$ equal to 0.51264 ($\varepsilon_{Nd(i)}$ = + 3.7), (3) a $^{206}Pb/^{204}Pb_{(i)}$ value of 18.24, $^{207}Pb/^{204}Pb_{(i)}$ of 15.55 and $^{208}Pb/^{204}Pb_{(i)}$ ratio of 38.01. These values are comparable to enriched mantle sources, suggesting that the grano-diorite originated from a mantle source contaminated by continental crust. The bulk chemical composition of the SAB crystalline basement granodiorite is thus

compatible with that of arc magmas resulting from mixing of different proportions of a mantle component with a subduction/crustal component (e.g. Marchesi et al., 2007).

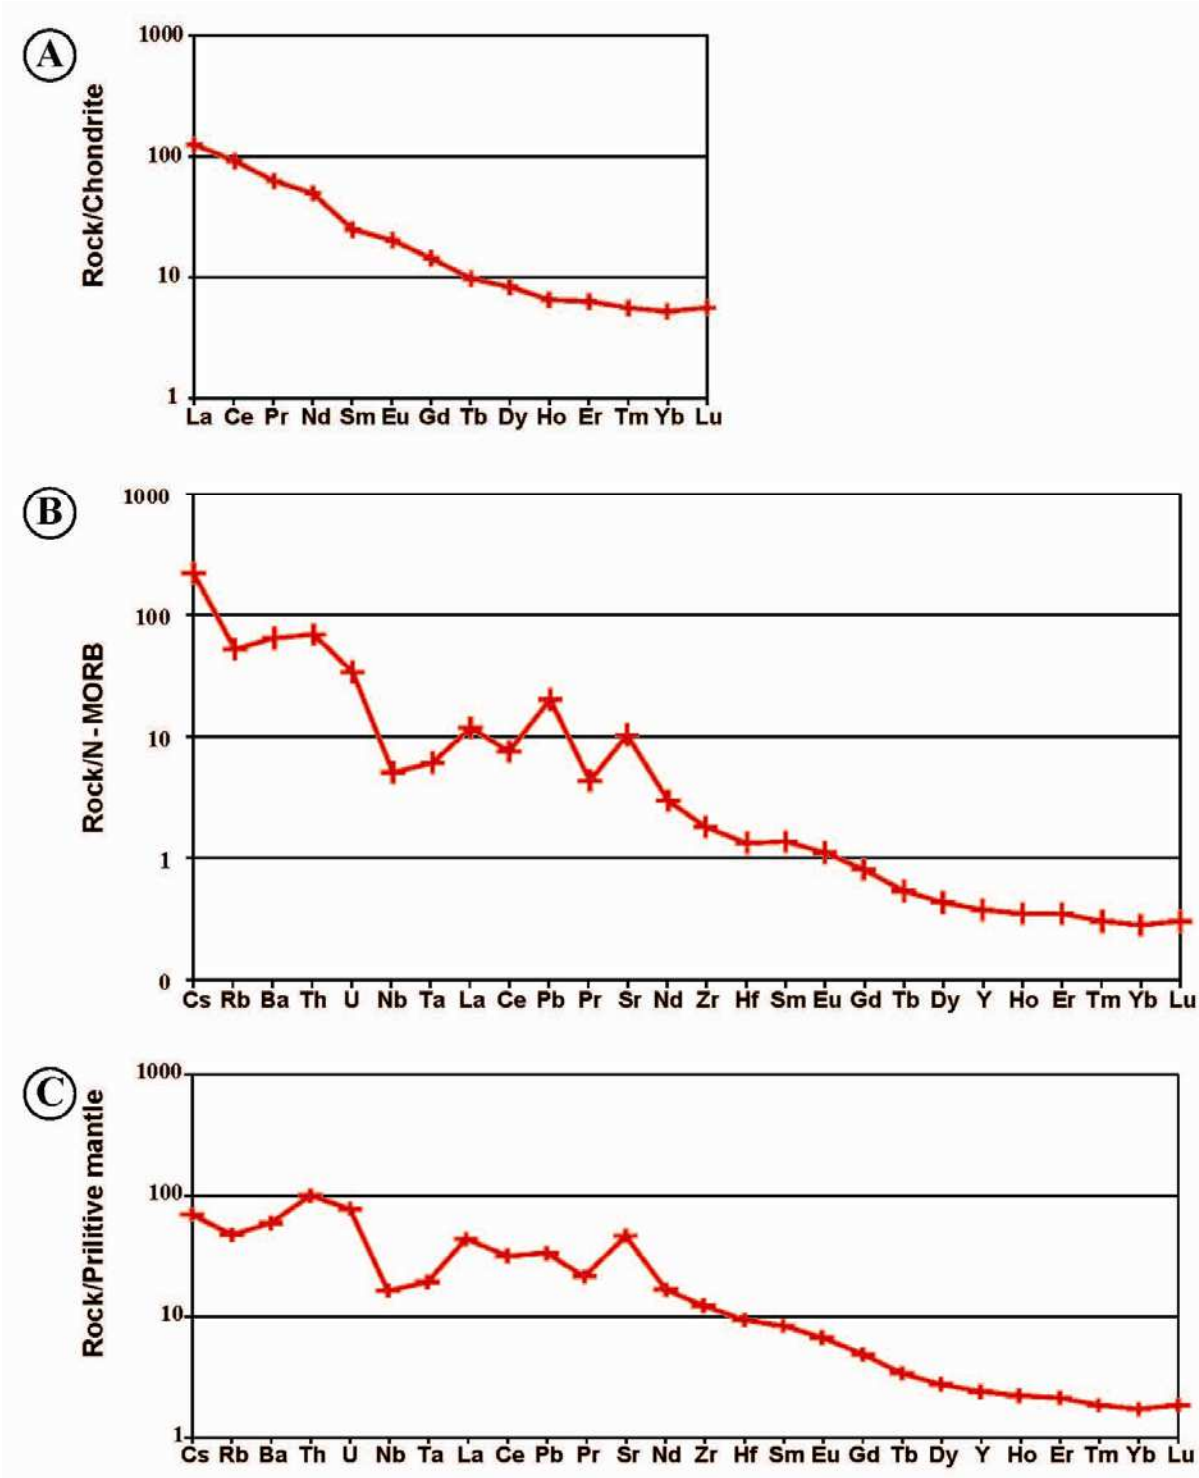

Figure 50 - Chondrite normalized REE and N-MORB and primitive mantle normalized multi-element spider diagrams of the granodiorite sample ARL-10-33. Normalizing values are from Sun and McDonough (1989).

1.5.2.2 $^{40}Ar/^{39}Ar$ Geochronology of sample AR-04-64 leucogranite

Two experiments have been undertaken on this sample (1) a single-grain laser experiment (H446) and (2) a furnace experiment (M1907) (**Figure 51**, **Table 15**). Identically as for sample AR-03-62 exposed below, the two (laser and furnace) experiments show a double hump shape. Experiment H446 shows (1) a low temperature part with younger age steps (~149 Ma), which represents less than 4% of released ^{39}Ar (steps 9-10). The rest of the spectra is comprised between 149 and 158 Ma, with (1) a low temperature age maximum of c. 156 Ma; (2) a medium temperature age minimum of c. 147-148 Ma in steps 9-10; (3) a HT maximum of c. 157-158 Ma (for the last three steps). Despite this spread, a weighted mean age of 153 ± 2 Ma (2σ) (MSWD 4.95) is calculated. The normal isochron is within error, with an age of 154 ± 2 Ma (2σ) (MSWD 1.78). The good agreement between these two ages, and the proximity with minimum age of HT steps validates an Upper Jurassic age for muscovite of the leucogranite body.

Similarly to this laser experiment, the furnace experiment (M1907) shows a minimum age of 150 Ma in the last three steps, with a weighted mean age of 142 ± 4 Ma (2σ) (MSWD 12) and an isochron age of 139 ± 5 Ma (2σ) (MSWD 9.0). The spread in ages along with a greater MSWD value shows a more important resetting in this sample than in experiment H446, which is therefore variable from one sample to another. Nonetheless, the minimum age of ~150 Ma is in agreement with the laser results (experiment H446).

1.5.2.3 $^{40}Ar/^{39}Ar$ geochronology of sample AR-03-62M micaschist

Muscovite AR-03-62M laser $^{40}Ar/^{39}Ar$ spectrum is complex (**Figure 51**, **Table 15**), showing a double-hump shape. It shows: (1) a low temperature part with a younger age step (105 Ma), which represents less than 5% of released ^{39}Ar (step 1). The rest of the spectra is comprised between 131 and 148 Ma, with (1) a low temperature age maximum of c. 140 Ma (obtained for two consecutive steps in **Figure 51**, steps 4-5); (2) a medium temperature age minimum of c. 130 Ma (steps 7-8); (3) a HT maximum of c. 148 Ma (steps 11-12). This latter age is considered as a minimum age for muscovite closure. No correlation is found between the K/Ca ratios and ages of individual steps, therefore it does not seem possible to discriminate between several muscovite generations from this dataset as is illustrated by fine section observations (**Figures 46C** & **D**). The isochron age of 149 ± 5 Ma (2σ) (MSWD 2.5) supports the interpretation of a minimum age of crystallization at c. 149 Ma.

1.5.2.4 $^{40}Ar/^{39}Ar$ geochronology of sample AR-04-62 orthogneiss

The gneiss muscovite furnace $^{40}Ar/^{39}Ar$ dating experiment (M1905) (**Figure 51**, **Table 15**) exhibits a double-hump shape with (1) low temperature steps 1-3 < 135 Ma, representing less than 4% of released ^{39}Ar, (2) a LT maximum of 155 Ma (step 5), (3) a MT minimum of 142 Ma (steps 7-8) and (4) a HT maximum of 152-153 Ma in the steps 12-14. Despite this spread a weighted mean age of 148 ± 3 Ma (2σ) (MSWD 10) and a corresponding isochron of 150 ± 3 Ma (2σ) (MSWD 7.2) can be calculated. This latter isochron age is within error of the HT spectra minimum age. The gneiss biotite exhibits a flat spectrum, with a plateau age using 95% of released ^{39}Ar, of 123 ± 2 Ma (2σ) (MSWD 1.4). The isochron plot provides a similar within-error age estimate of 121 ± 4 Ma (MSWD 1.3) and the inverse isochron gives an age of 121 ± 5 Ma (2σ) (MSWD 1.4) with an upper intercept $(^{40}Ar/^{36}Ar)_0$ = 320 ± 19 close to atmospheric value. These ages are in good agreement, which gives good insight in the cooling process of the orthogneiss with biotite closure at 120-123 Ma. We interpret this to occur during gneiss retrogression at T ≈ 400°C (Villa, 1998), which temperature is coherent by garnet-biotite thermometry (section 4).

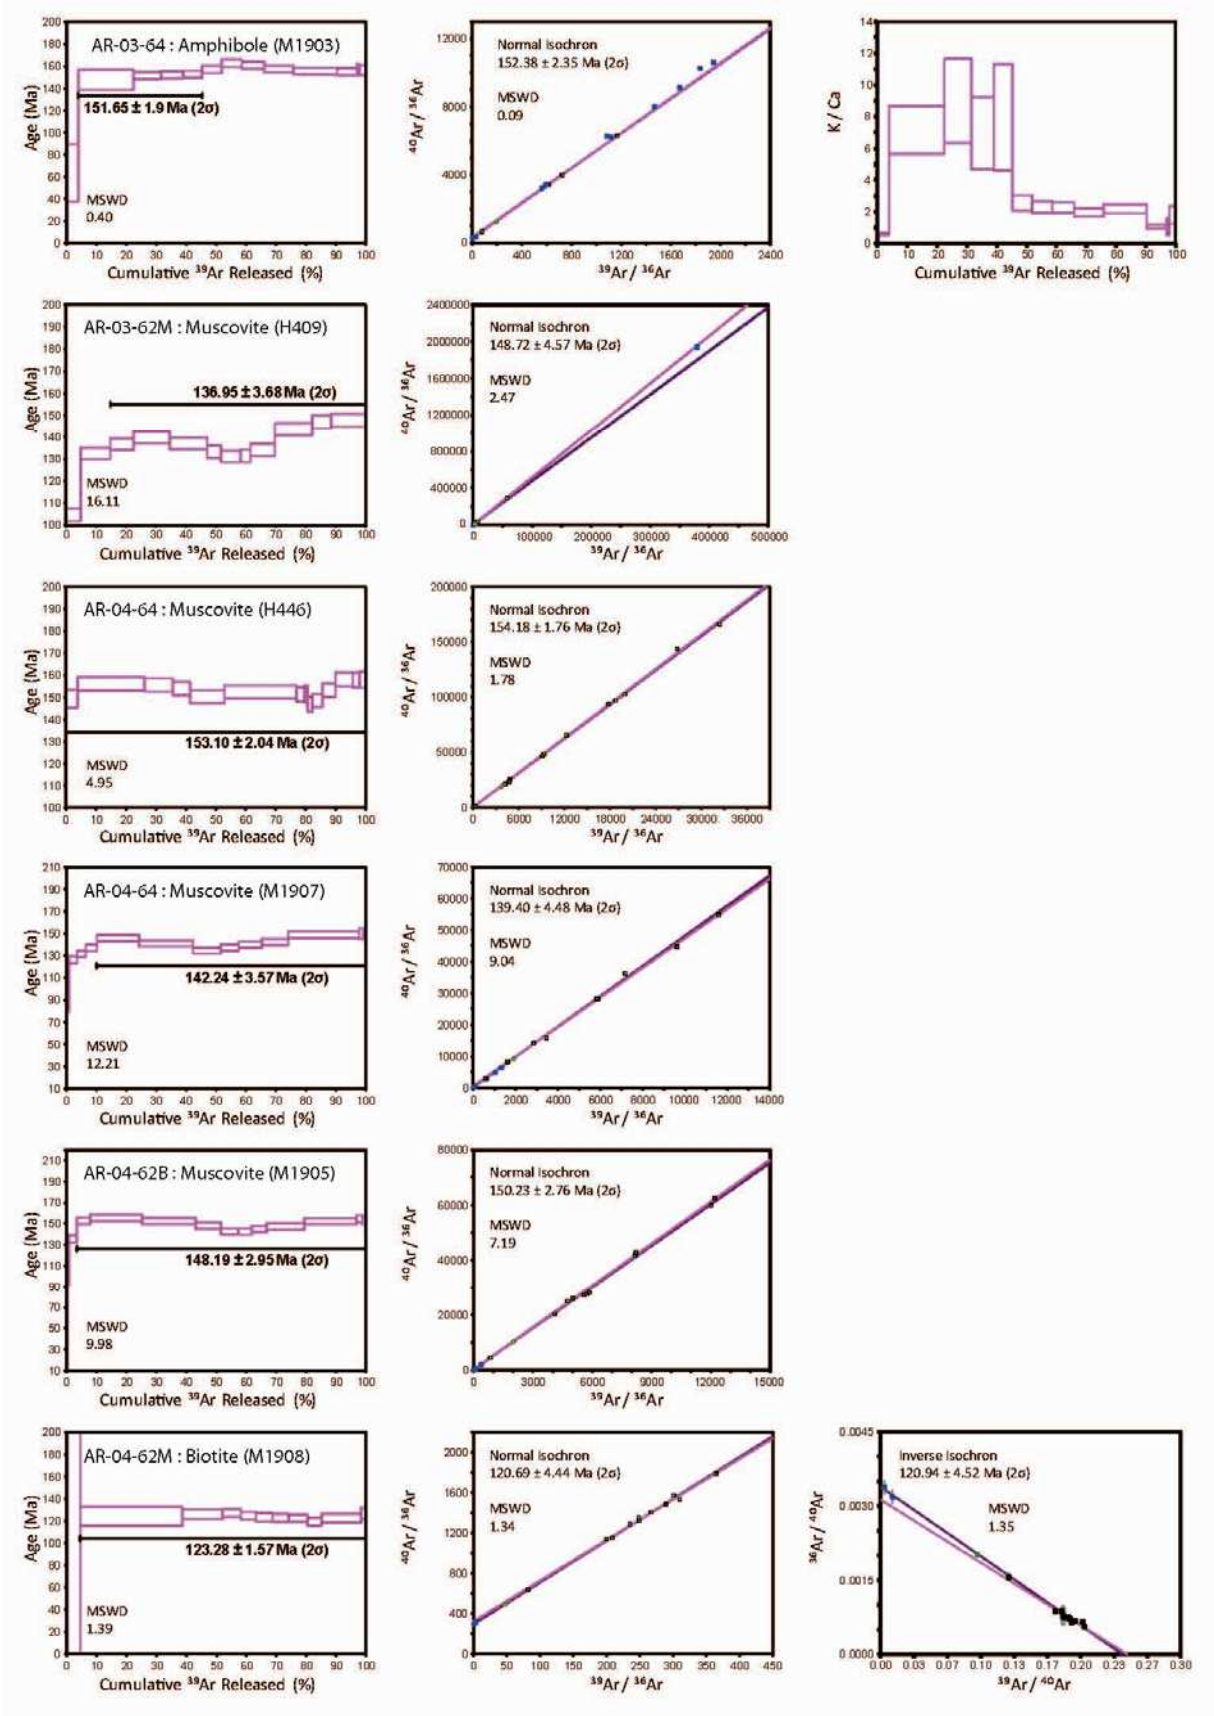

Figure 51 - $^{40}Ar/^{39}Ar$ age spectra, normal isochrones and Ca/K spectra of dated samples. Locations of samples are shown on Figure 45.

1.6 Discussion

The origin of the different rock types found in the Tsaghkuniats region is unconstrained in time as well as the geodynamic processes responsible for their formation. Before the present paper, only the age obtained by Baghdasarian and Ghukasian (1983) obtained using the Rb-Sr isochron method on the Bjni migmatite-granite suggests a Proterozoic (610 ± 36 Ma) origin for the metamorphism and magmatism undergone by the SABCB. The metamorphic evolution of the SABCB is investigated here for the first time with combined U/Pb and $^{40}Ar/^{39}Ar$ geochronological data. In addition, we also show here for the first time a well-constrained PT evolution featured by a decompression path from mid-crustal (M1) MP-MT conditions to sub-surface (M2) HT-BP conditions. This metamorphic history coincides with calc-alkaline magmatism along the northern margin of the SAB. In the following discussion we propose significance for the above ages as well as structural observations, and their implication for the tectonic evolution of the SAB.

1.6.1 Significance of double-hump shaped muscovite Ar spectra

The HT part of the white mica spectra all show minimum ages similar within error to the age of the granodiorite, which is interpreted as a M1 regional metamorphic imprint coinciding with intrusion emplacement at c. 153 Ma. Granodiorite intrusion occurred at c. 153 Ma, as shown by within error U/Pb Tera-Wasserburg age of 153 ± 2 Ma on zircon and amphibole $^{40}Ar/^{39}Ar$ weighted mean average of 150 ± 6 Ma (see section 5.2.1). The M1 event is featured by complex $^{40}Ar/^{39}Ar$ ages in intruded schists, as shown by the 153 Ma, 142 Ma and 149 Ma mean weighted averages of two leucogranite muscovites and a micaschist muscovite sample, respectfully AR-04-64 and AR-04-62 (**Figure 52**). However, mylonitic muscovites exhibit complex spectra with two age maxima, in the LT and HT steps. This shape does not coincide with variations in K/Ca and Cl/K ratios of the sample (see Supplementary Data 2). It is interpreted as resulting from argon diffusion during mylonitization, which lowers the age (e.g. Dodson, 1973; Kramar et al., 2001; Mulch et al., 2002 and Sanchez et al., 2011 for a complete analysis of the effect of mylonitic deformation on argon spectra). Chemically zoned grains (or grain populations) may contain heterogeneous argon compositions because of zonation induced by recrystallization and re-equilibration with their environment (Giorgis et al., 2000; Vance et al., 2003) or because of

chemically diverse zones of the grain having different retention properties (Villa et al., 1996). Such lattice defects form the boundaries of micro-structurally controlled diffusion segments and reduce the physical (observed) grain size and, hence, the characteristic length scale for argon diffusion (Reddy and Potts, 1999). This conclusion is consistent with the results of Dunlap and Kronenberg (2001) who speculated that grain segmentation affects the ability to retain argon in micas deformed under laboratory conditions. However, there are currently no experimental data in the earth science literature for noble gas behavior in strained solids. Field structural observations and microscope or Electron back-scatter (EBS) imaging of sample AR-04-64 (**Figure 46C**, **D** & **G**) provide further insights into the internal deformation and recrystallization of micas. Mylonitic deformation is found to occur during (1) top-to-north deformation and (2) normal sense of shear during doming. The top-to-north deformation is mainly featured by growth of M1 muscovite neo-cysts within the foliation forming at T > 500°C. Therefore, this should not be responsible of argon diffusion. In contrast, the extensional phase starts in HT conditions, and ends with brittle deformation. Therefore, M1 muscovite has been severely deformed during M2 (150-130 Ma) at a temperature between 200°C and 500°C, which has been noted to be a temperature range in which ductile deformation may partially reset muscovite grains by neo-crystallization and diffusion in intra-granular micro-fractures especially between 380°C and 400°C (Kramar, 2002; Mulch et al., 2002). This phase of mylonitization ends before the post-kinematic (M3) biotite AR-03-62b that crystallized at 360-460°C and 2 ± 1 kbar (section 4), which yields plateau age of 123 ± 2 Ma.

Therefore, from the example of the SABCB, we propose that mylonitic deformation can be bracketed in time by the $^{40}Ar/^{39}Ar$ dating method, because we were able to date minerals formed before (the M1 granodiorite minerals) and after (M3 biotite) the main mylonitization phase. The HT part of the spectra yields a minimum age for muscovite crystallization, here ~155 Ma during the M1 metamorphic phase (AR-04-64 muscovite). The medium temperature minimum of the spectra yields a maximum age for the low temperature stage of mylonitization, here ~130 Ma (from sample AR-03-62 muscovite). Nevertheless, it is still questionable whether ages obtained correspond to the original formation of the micaschists or their metamorphism/deformation.

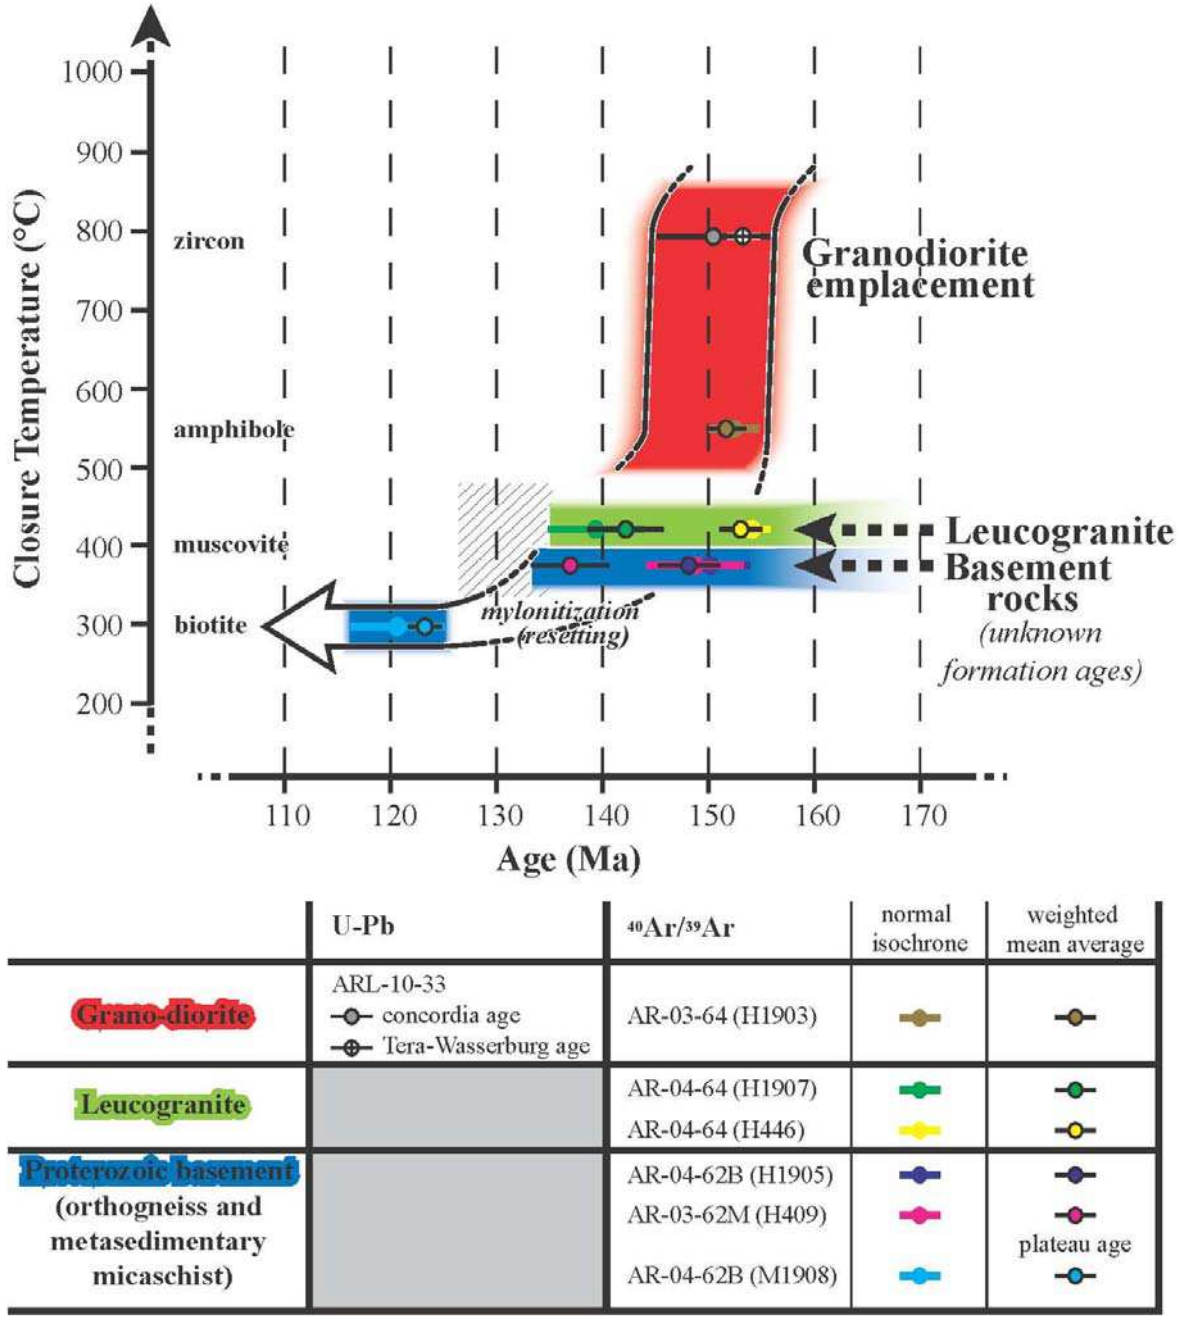

Figure 52 - Cooling model for $^{40}Ar/^{39}Ar$ and U-Pb dating results with error margins.

It is important to point out that despite efforts to constrain the entire metamorphic evolution of the Tsaghkuniats massif the protolith age of these micaschists is still to be determined. Two scenarios may be suggested, either (1) the micaschists were indeed originally deposited and incorporated within the Proterozoic basement as forwarded by Baghdasarian and Ghukasian (1983), and later metamorphosed through the regional metamorphism described above or (2) they represent the lateral equivalent of Upper Devonian-Permian formations in this area which are preserved (unmetamorphosed) farther

south along the northern edge of the Araks Valley (Sosson et al., 2010). To solve this issue, punctual U-Pb dating of zircon and/monazite mineral phases in these micaschists should be undertaken.

1.6.2 Tectonic significance of the PT-t history

The above age data are correlated together (**Figure 52**) and to the PT path to define a PTt path on **Figure 53**. The entire metamorphic cycle determined, from burial to exhumation, can be bracketed between 160 Ma and 120 Ma. Minimum ages preserved in M1 muscovite of metapelites imply initial burial of metasediments between 160 Ma and 155 Ma at M1 peak in MP-MT conditions (25°C/km). Rapid exhumation is suggested by decompressional melting and formation of leucogranites with injection of grano-diorites at c. 153 Ma. Exhumation is more or less isothermal and is followed by M2 doming at LP-HT conditions, which is bracketed between 150 Ma and 130 Ma, from muscovite $^{40}Ar/^{39}Ar$ spectra. Further cooling is featured by age of M3 biotite recrystallization at 123 Ma, which is linked to temperatures of 400°C from garnet-biotite exchange thermometry.

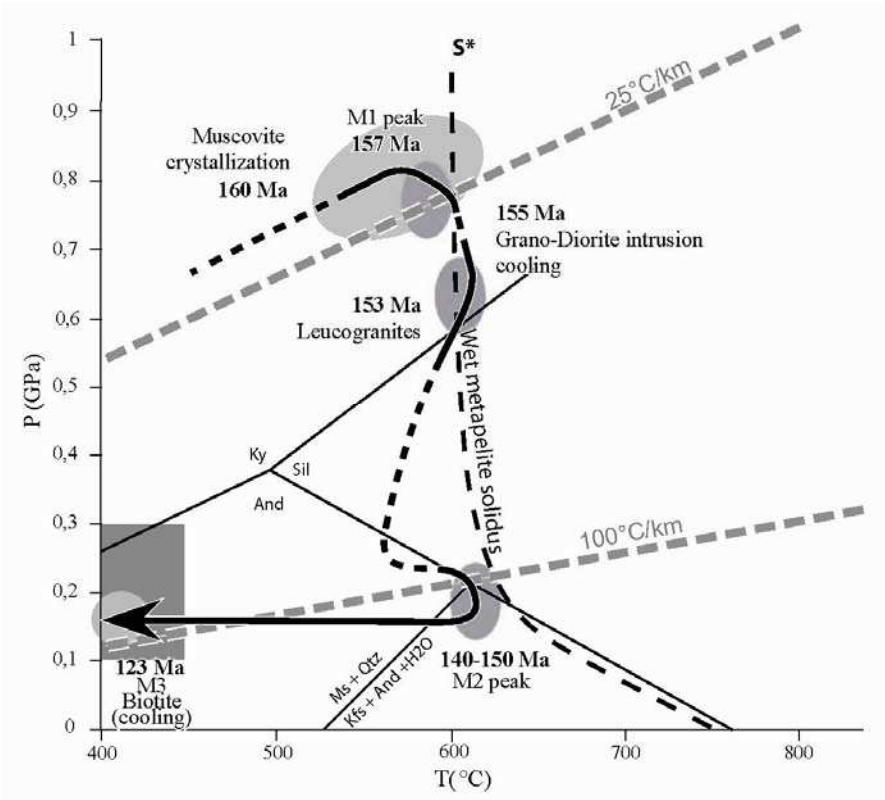

Figure 53 - PT-t path including metamorphic (Figure 48C), $^{40}Ar/^{39}Ar$ and U-Pb age data.

This PT path is quite uncommon, though it can be supported by the peculiar tectonic context of the Tethys-Caucasus region during the Late Jurassic to Early Cretaceous (**Figure**

54). The region is characterized by north-dipping subduction of the Tethyan oceanic domain below the southern Eurasian margin since the Carboniferous, and until the Middle Cretaceous (Rolland et al., 2011; 2012). A north-dipping intra-oceanic subduction is evidenced by the presence of an ophiolite formed in a back-arc setting during the Late Jurassic north of the SAB (Galoyan, 2008; Rolland et al., 2009a; 2009b, 2011; Hässig et al., 2013; Topuz et al., 2013). Such north-dipping subductions are also suggested at the scale of the Northern Paleotethys Ocean, which would be totally subducted by the Middle Cretaceous times. Here, the north sense of shear and MP-MT metamorphism, correlated to calc-alkaline magmatism, are in agreement with a south-dipping subduction zone below the SAB since at least 160 Ma, which evidence vanishes in the Early Cretaceous at 123 Ma. The magmatics could alternatively be explained by hot-spot activity. We discard this possibility, however, because of the long duration (minimum 37 Ma) of the metamorphic episode. In this period the SAB was a mobile tectonic block in the Tethyan realm that had separated from Africa. This is not in agreement with a stable position above a hot-spot during ~40 Ma. Further, the calc-alkaline nature of magmatic rocks is not in agreement with hot-spot geochemistry. North-dipping subduction below the southern margin of SAB is equally unlikely at this time as such a subduction would have led to convergence of SAB with Gondwana.

Therefore, we propose the presence of a third subduction zone in the Neotethyan realm between the SAB and the north-dipping intraoceanic subduction zone from Middle Jurassic to Early Cretaceous. We suggest that this south-dipping subduction below the SAB may have also been a motor of SAB-Eurasia convergence. This subduction, which is not observed along the rim of Taurides, may (1) be hidden by latter sedimentary deposits and/or nappe structures, or still to be evidenced, or (2) be due to a corner effect of the northward drifting SAB at the boundary with the Iranian part of Eurasian margin.

The two-stage metamorphic evolution observed in the SABCB resembles that observed in the active margin of retreating subduction zones such as in the Agean domain in the E-Mediterranean Sea (e.g. Jolivet and Brun, 2010) and may also be compared to multistage metamorphism linked to crustal deformation in Trans-amazonian and Brasiliano metamorphism (Neves et al., 2006). In these contexts, HT metamorphism is shown to occur shortly after HP-BT metamorphism, and is correlated to back-arc type extension. The retreat of the subducting slab, the steepening of the subduction due to slab pull, would result in the vanishing of metamorphism after a short period (approximately 10-20 Ma as throughout the

Agean domain). A similar scenario is proposed for the northern margin of the SAB in the Late Jurassic to Early Cretaceous: firstly, because of a similar timing and PT path, with a final extensional context featured by metamorphic domes, and secondly by the subduction of the old oceanic crust that is likely to behave in a similar way as the Neotethys in E-Mediterranean domain in the Cenozoic. In such contexts, the slab density is assumed to drive the subduction.

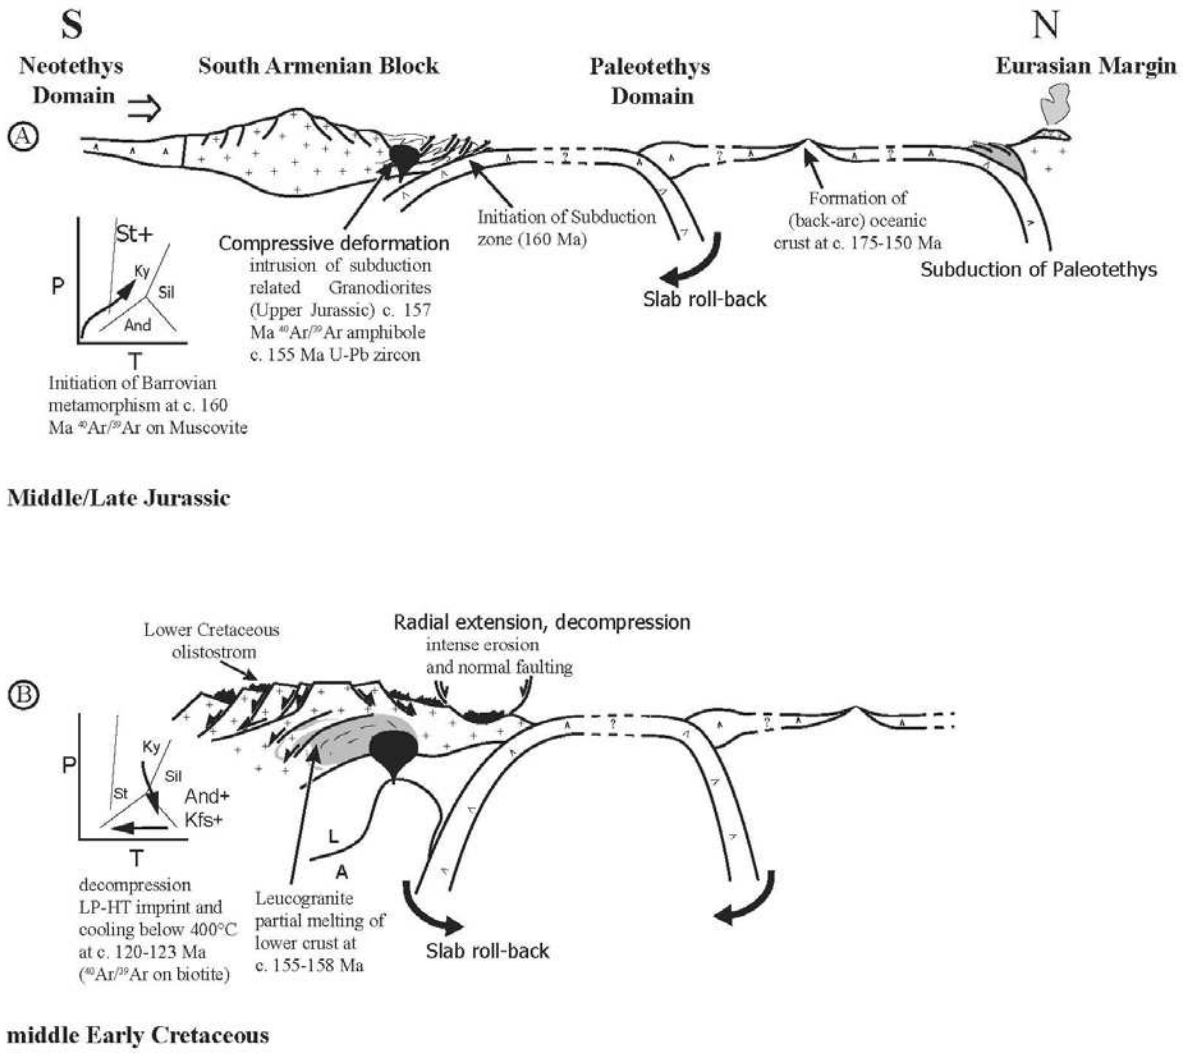

Figure 54 - Sketch geodynamic model proposed for the SAB (Lesser Caucasus) from Middle Jurassic to Upper Cretaceous-Paleocene times.

1.7 Conclusion

We show here for the first time an amazingly young multi-stage metamorphic evolution for this region preserved in the SABCB, fully occurring during the Late Jurassic and Early Cretaceous times. Geochronological data show it to be unrelated to the Cimmerian orogeny. (1) First M1 metamorphism is featured by Barrovian (staurolite-kyanite) MP-MT conditions at 157-160 Ma and intrusion of dioritic magmas at 150-156 Ma. (2) Near-adiabatic decompression PT path is featured by partial melting and production of leucogranites at 153 Ma, followed by M2 (andalusite-K-feldspar) HT-BP metamorphism. This phase of shearing and recrystallization is ascribed to doming at 130-150 Ma and cooling at 400°C by 123 Ma (M3). Structural evidence shows (1) north-verging shearing during M1 and (2) radial extension during M2. This metamorphic evolution is interpreted as featuring south-dipping subduction below the SAB, as evidenced by emplacement of relatively hot subduction related granodiorite in a way similar to Mediterranean subduction zones in the Cenozoic.

Chapitre 5* - *Histoire de la branche nord de Néotéthys avant son obduction.

« Une théorie ne ressemble pas plus à un fait qu'une photographie ne ressemble à son modèle. »

Edgar Watson Howe

V.1 Article 5 – From ocean crust geneis to obduction initiation: history of the northern branch of Neotethys prior to the Late Cretaceous obduction event in NE Anatolian and Lesser Caucasus regions

Au regard des nouvelles données géologiques obtenues dans cette thèse, nous proposons une synthèse justifiant une configuration tectonique réaliste du contexte de pré-obduction dans la région du Petit Caucase-NE Anatolie. Ce travail de synthèse est rendu nécessaire pour bien fixer le cadre d'une modélisation numérique de l'obduction.

L'évolution de la branche nord de la Néotéthys, depuis sa genèse jusqu'à son obduction partielle, peut être déduite depuis les études structurales, stratigraphiques, géochimiques et géochronologiques relatives aux ophiolites préservées, au volcanisme de la marge eurasienne au nord, ainsi qu'aux roches métamorphiques en position basale sous l'ophiolite (la semelle) et celles appartenant à la marge chevauchée par la nappe ophiolitique au sud. Ces études convergent vers un modèle dans lequel une seule nappe ophiolitique, d'âge Jurassique moyen à Crétacé inférieur, se met en place au milieu du Crétacé supérieur, 90~83 Ma, sur le SAB-TAP (Sokolov, 1977; Özgül *&* Turşucu, 1984; Bergougnan, 1987; De Wever *et al.,* 1987; Bozkuş, 1998; Harris *et al.,* 1994; Aktimur *et al.,* 1995; Chiari *et al.,* 1997; Okay *&* Tüysüz, 1999; Chiari *et al.,* 2000; Danelian *et al.,* 2000; 2008; 2012; 2014; Bill *et al.,* 2001; Bozkurt *&* Mittwede, 2001; Önen, 2003; Göncüoğlu *et al.,* 2006; Özen *et al.,* 2006; Galoyan *et al.,* 2007; 2009; Asatryan *et al.*, 2009; 2010; 2011; Galoyan, 2008; Gedik, 2008; Moix *et al.,* 2008; Rolland *et al.,* 2009a; 2009b; 2010; Sosson *et al.,* 2010; Çelik *et al.,* 2011; Robertson *&* Ustaömer, 2012; Aslan *et al*., 2011; Hässig *et al.,* 2013; 2014; Moix *&* Goričan 2013; Parlak *et al.,* 2013). Cette nappe ophiolitique, au sud de la zone de suture Izmir-Ankara-Refahiye-Amasia-Sevan-Akera, s'étendrait sur au moins 700 km de large et chevaucherait de 100 à 200 km le bloc continental SAB-TAP (Lordkipanidze *et al.*, 1989; Galoyan, 2008; Sosson *et al.*, 2010; Rolland *et al.*, 2011; Danelian *et al.*, 2012; Hässig *et al.*, 2013; 2014).

Les roches magmatiques et ultrabasiques composant cette nappe ont une géochimie qui indique une formation dans un contexte de SSZ à arrière-arc. Nous en déduisons donc l'existence d'une subduction intra-océanique pendant la formation de l'ophiolite. Comme nous l'avons vu précédemment, celle-ci se formerait dans un contexte de dorsale océanique lente

au sein d'un domaine océanique préexistant. Par ailleurs, au cours de la phase d'accrétion océanique, au Jurassique moyen, ce domaine océanique est également en subduction sous l'Eurasie au nord comme l'indique une forte activité volcanique sur cette marge. L'action combinée du retrait de panneau plongeant, (sous la subduction intra-océanique), et de la traction du panneau plongeant sous l'Eurasie au nord peut être considérée comme le moteur de cette ouverture.

Cependant, ce modèle souffre de l'absence d'un arc volcanique préservé qui aurait été formé au droit de la subduction intra-océanique. Nous expliquons cette absence par l'écaillage de cet arc et son incorporation dans la semelle d'obduction sous l'ophiolite au cours de sa mise place. On suppose que les roches métamorphiques de bas degré de Erzincan, les schistes bleus de Stepanavan et les amphibolites à grenat d'Amasia correspondent à cet arc volcanique manquant (Galoyan *et al.*, 2007; Rolland *et al.*, 2009a; Hässig *et al.*, en revision).

Des études récentes fournissent des arguments pour un modèle intégrant une subduction vers le sud sous la bordure nord de la SAB-TAP avec la mise en place d'intrusions de granodiorites caractéristiques de ce contexte au Jurassique inférieur (c. 160 Ma). La continuité à l'ouest de cette structure en NE Anatolie est incertaine, ainsi à ce stade nous présentons une alternative, un modèle sans subduction plongeant au sud et l'autre l'incluant. En effet, cette zone de subduction pourtant étayée en Arménie pourrait n'être qu'un 'détail' de bordure à l'échelle du bloc SAB-TAP (sauf si les travaux futurs indiquent le contraire).

Dans la quasi-totalité des affleurements ophiolitiques, deux suites magmatiques sont mises en évidence : (1) la croûte océanique tholéiitique surmontée de (2) coulées basaltiques ou tufs volcaniques avec des tendances alcalines. Les datations radio-chronologiques ainsi que bio-stratigraphiques montrent que la mise en place de cette deuxième suite se produit dans un environnement océanique avant l'obduction des ophiolites du Jurassique au début du Crétacé supérieur. Ces roches alcalines plus jeunes, surmontant le plancher océanique est un élément explicatif important de l'obduction. En effet, la modélisation numérique montre qu'il est nécessaire de réchauffer la lithosphère océanique pour qu'elle puisse être obduite sur la marge continentale. Les amphibolites à grenat, dans la semelle de la croûte océanique charriée, indiquent en effet des conditions PT particulièrement chaudes.

Afin de présenter une modélisation numérique dans la partie suivante, qui permettra de tester les différents paramètres entrant en jeu dans le processus d'obduction, nous fournissons ici un modèle conceptuel argumentant la configuration pré-obduction pour la mise en place de la nappe ophiolitique de la région du Petit Caucase-NE Anatolie.

Cette analyse fait l'objet d'une publication en révision à *Geological Society of London, Special Publications*.

From ocean crust genesis to obduction initiation: history of the northern branch of Neotethys prior to the Late Cretaceous obduction event in the NE Anatolian and Lesser Caucasus regions

Abstract

In light of new geological data, we argue for an innovative tectonic setup just prior to the Northern Neotethys obduction event in the NE Anatolian and Lesser Caucasus area. At several locations along the northern Neotethyan suture (Ankara-Erzincan-Amasia-Sevan-Akera suture zone), slivers of preserved unmetamorphozed relics of now disappeared northern branch of the Neotethys oceanic domain are obducted over the northern edge of the South Armenian Block (SAB) and Taurides-Anatolides Platform (TAP) margins to the south, occurring as scatted ophiolite bodies. Recent studies have shown that the ophiolitic bodies are formed of similar lithologies of Middle Jurassic ages (c. 175~165 Ma) all bearing LILE-enriched MORB chemical compositions. This extensive data base supports a model in which these ophiolites derive from a single obducted nappe. This model is equally backed by metamorphic PT-t paths of sole lithologies under the suture zone ophiolite outcrops. Equivalent paleontological datings of sediment deposits directly under or sealing the obduction contact, respectively of pre- and post- ophiolite emplacement, also comfort this model by temporally linking the distant ophiolite outcrops. General emplacement during early-Late Cretaceous times (c. 92~88 Ma) is well argued. A south dipping subduction under the SAB which shortly predates obduction has recently been proposed from the metamorphic and magmatic evolution preserved in the SAB crystalline basement, establishing a model incorporating divergent subductions at least from late-Middle Jurassic to Early Cretaceous times (c. 160~130). Emplacement of large alkaline pillow basalts directly on the oceanic crust is dated Early to mid-Cretaceous (c. 120~100 Ma). These datings argue for the existence of mantle heat flows, which may be responsible for decrease in density of the 80 Ma old oceanic lithosphere prior to its obduction onto SAB-TAP. Still, with these snapshots of the closing of this oceanic domain, 80 Ma of history between genesis and emplacement are poorly constrained. We undergo a detailed review of recent data to further constrain the structural and geodynamic evolution of this sector in order to define a tectonic setup just prior to the obduction event.

keywords : obduction; subduction; Neotethys; ophiolite

1.1 Introduction

The evolution of northern Neotethys can be deduced from the structural, geochemical and geochronological studies pertaining to preserved oceanic crust domains (ophiolites) obducted as in the Lesser Caucasus and in NE Anatolia and of the metamorphic rocks beneath these ophiolites. These studies yield key time and paleogeographic constraints for the evolution of Neotethyan basins from the East Mediterranean area to the NW Himalayan belt (Şengör & Yılmaz 1981; Ricou *et al.* 1985; Dercourt *et al.* 1986; Ricou 1994; Okay & Tüysüz 1999; Stampfli *et al.* 2001; Robertson 2004; Hafkenscheid *et al.* 2006; Barrier & Vrielynck 2008; Galoyan *et al.* 2009; Rolland *et al.* 2010; Sosson *et al.* 2010; Hässig *et al.* 2013). In this area, ophiolites are mainly of supra-subduction zone (SSZ) type. They provide chronological constraints related to oceanic crust formation by repetitive extension in a fore- and/or back-arc context, linked to the behavior of an intra-oceanic subduction. The study of these remarkable objects also contributes to the understanding of oceanic closure, particularly ophiolite emplacement processes. Actually, (i) the timing for ophiolite obductions in the Middle East subduction zones determined by these studies supports sub-simultaneous ophiolite obductions along the several subduction zones at c. 90 Ma (Galoyan 2008; Rolland *et al.* 2009a; Topuz *et al.* 2013; Aslan *et al*., 2011; Hässig *et al.* submitted). (ii) Further, the size of the reconstructed obducted ophiolitic nappe of the northern Neotethys segment (south of the Izmir-Ankara-Refahiye-Amasia-Sevan-Akera suture zone) is of at least 700 km in length and 100-200 km in width (Lordkipanidze *et al.* 1989; Galoyan 2008; Sosson *et al.* 2010; Rolland *et al.* 2011; Danelian *et al.* 2012; Hässig *et al.* 2013, 2014). When considering the distance between the suture zone and the ophiolitic front (at its present day location), a minimum of 100 km is needed to reach areas such as Vedi (Armenia) or Hınıs (Turkey) and up to 200 km are necessary to reach Khoy (Iran), zones where obduction fronts have been identified (Galoyan 2008; Rolland *et al.* 2009; Sahakyan *et al.* 2013). The studies converge to constrain a 90~83 Ma interval of time for obduction of a single ophiolitic nappe of Middle Jurassic to Early Cretaceous age (Sokolov 1977; Özgül & Turşucu 1984; Bergougnan 1987; De Wever *et al.* 1987; Bozkuş 1998; Harris *et al.* 1994; Aktimur *et al.* 1995; Chiari *et al.* 1997; Okay & Tüysüz 1999; Chiari *et al.* 2000; Danelian *et al.* 2000, 2008, 2012, 2014; Bill *et al.* 2001; Bozkurt & Mittwede 2001; Önen 2003; Göncüoğlu *et al.* 2006; Özen *et al.* 2006; Galoyan *et al.* 2007, 2009; Asatryan et al. 2009, 2010, 2011; Galoyan 2008; Gedik 2008; Moix *et al.* 2008; Rolland *et al.* 2009a, b, 2010; Sosson *et al.* 2010; Çelik *et al.* 2011; Robertson &

Ustaömer 2012; Aslan *et al*., 2013; Hässig *et al.* 2013, 2014; Moix & Goričan 2013; Parlak *et al.* 2013).

Given the ~80 Ma time span which separates the setup of oceanic lithosphere and the onset of the obduction of the ophiolitic nappe, it seems evident that multiple geodynamic events may have affected this domain. The emplacement of vast bodies of preserved (unmetamorphosed) oceanic crust lithologies of such an old (~80 Ma) and dense oceanic crust over large distances onto a continental crust is a puzzling geological problem. In this paper we propose a review and implement new findings to build a coherent tectonic setup of obduction initiation for the Northern Neotethys ophiolite belt.

1.2 Main tectonic units

As the results of the obduction and collision stages in the Lesser Caucasus and Eastern Anatolides (**Figures 55** and **56**), four main tectonic units are classically distinguished along the belt. We present them from north to south as following.

1.2.1 The Eurasian margin

In the Eurasian part of the Lesser Caucasus, the basement formations are quite similar to those known all along the Eurasian margin (Sosson *et al.* 2010 for a review). It corresponds to the variscan basement and it is covered by thick and mainly calc-alkaline volcanogenic series of Bajocian to Santonian age evidences the subduction of the Tethys oceanic domain (e.g. Adamia *et al.* 1981 for a review). During this period, an active continental margin domain called the Somkheto–Karabakh Island Arc characterized the northern Lesser Caucasus (Knipper 1975; Adamia *et al.* 1977, 1987; Ricou *et al.* 1986; Sosson *et al.* 2010). During the Early Cretaceous, tectonic erosion unroofed part of the plutonic unit of the active margin as result of significant uplift and denudation along the subduction zone (Sosson *et al.* 2010; Rolland *et al.* 2011). Subduction of more buoyant crustal domain, a spreading ridge of the back-arc basin or seamounts for example, could be responsible for such a change in the Eurasian active margin strain field as well as subsequent development of this unconformity (Rolland *et al.* 2011).

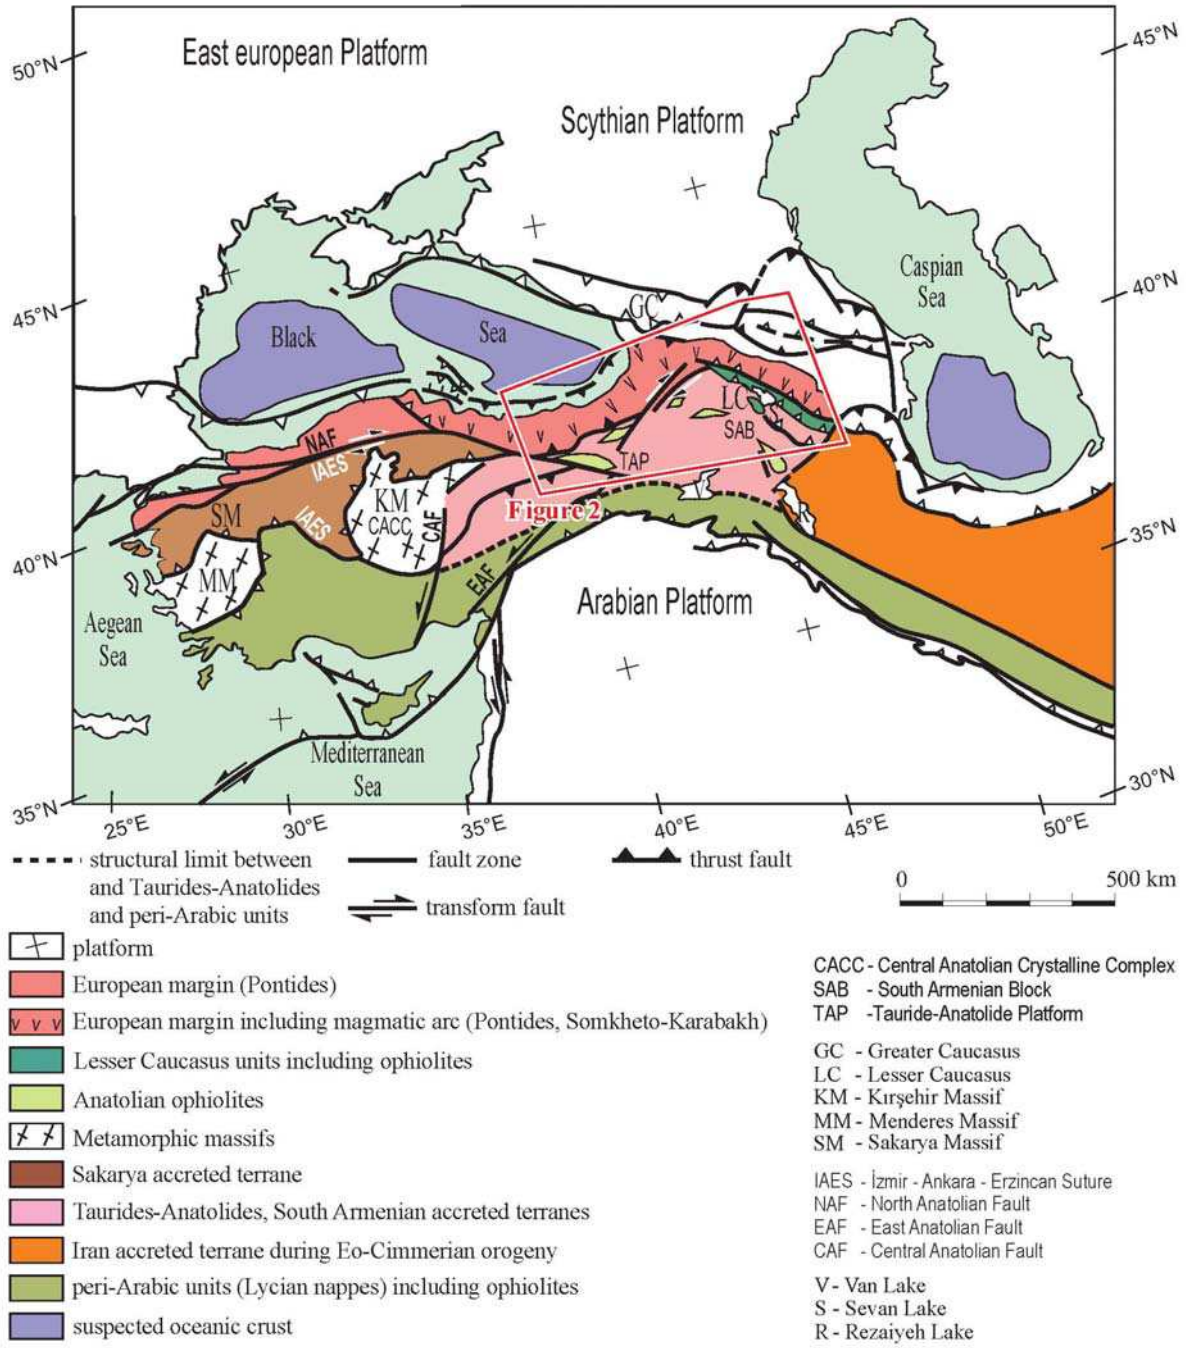

Figure 55 - Tectonic map of the Middle East–Caucasus area, with main blocks and suture zones, after Avagyan et al. (2005), modified. Location of Figure 56 is indicated.

The Eastern Pontides are interpreted as a part of the Sakarya Zone (Okay & Şahintürk 1997), and is the lateral equivalent of the Somkheto–Karabakh Island Arc. They also correspond to an active continental margin of Eurasia, which was formed as a result of northward subduction of Neotethys during the same time range spanning from Early Jurassic to Late Cretaceous (Şengör & Yılmaz 1981; Akıncı 1984; Okay & Şahintürk 1997). Onset of subduction is now well constrained. Both studies led in the Georgian side (Lesser Caucasus)

and the Turkish side (Pontides) show simultaneous calc-alkaline magmatic activity since the Early or Middle Jurassic (e.g. Adamia et al. 1981; Hess *et al.* 1995; Ustaömer & Robertson 2010; Nikishin *et al.* 2013; Ustaömer *et al.* 2013) although other ages were formerly proposed: Cenomanian–Turonian (Okay & Şahintürk 1997; Yılmaz *et al.* 1997) or Albian (Okay *et al.* 2006).

However, there is still a lack of consensus concerning the end of this subduction event in the Eastern Pontides/Eastern Anatolia region and onset of continental collision of TAP-SAB with the active margin of Eurasia. Proposals range from the end of the Late Cretaceous (Rolland *et al.* 2009, 2012) for the Lesser Caucasus, to the Paleocene (Okay & Şahintürk 1997) and the Eocene (Peccerillo & Taylor 1976; Şengör & Yılmaz 1981; Robinson *et al.* 1995; Yılmaz *et al.* 1997) for NE Anatolia.

Figure 56 - Structural map of the Lesser Caucasus-Eastern Pontides-Northeast Anatolides regions. Turkish zone modified from the 1:1 250 000 geological map of Turkey (MTA 2011); the Georgian-Armenian zone of the Caucasus after Sosson et al. (2010); the Iranian zone from Mederer (2013). The green shading represents proposed extent of the ophiolitic nappe.

1.2.2 The ophiolites

In Armenia, this unit is mostly composed, of interbedded reef limestones embedded in volcanic tuffs and lava flows of with intercalations of Middle to Upper Jurassic radiolarites (c. 170~145 Ma; Danelian *et al.* 2007, 2008, 2010, 2012; Asatryan *et al.* 2010, 2012), serpentinized peridotites intruded by gabbros, scattered cross-cutting plagiogranites in extensional shear zones and local accumulations of pillow lava flows in scattered emission centers, all of Middle to Late Jurassic age (c. 180-150 Ma on gabbros and basalts; Galoyan *et al.* 2009; Rolland *et al.* 2010; Hässig *et al.* 2013). Similar ages have been obtained for radiochronological dating of ophiolite lithologies and biochronology farther west in the prolongation of this unit in NE Anatolia, along the Izmir-Ankara-Erzincan segment of the northern tethyan suture zone (Çelik *et al.* 2011; Danelian *et al.* 2012; Topuz *et al.* 2013, 2014; Hässig *et al.* 2014; Moix & Goričan 2013) (**Figure 57**). Topuz *et al.* (2014) dated the plagiogranites at 182 ± 3 Ma and 175 ± 4 Ma by U-Pb on zircon by the latter authors, and Topuz *et al.* (2013) dated the gabbros at 174 ± 4 Ma by $^{40}Ar/^{39}Ar$ on hornblende. This lithological association is typical of a slow-spreading oceanic ridge.

Figure 57 - Tectonic map of Mesozoic Ophiolites and ophiolitic mélanges from the Tethyan realm in Turkey and adjacent areas (modified after Stampfli, 2000) and representative geochronological data from rocks of the ophiolitic mélanges as well as from metamorphic soles (modified after Çelik et al., 2011). 1.2.2.1 **Fore- or back-arc ophiolites?**

It has been suggested that the Karadağ ophiolites (NE Anatolia) are representative of a fore-arc environment due to their boninitic chemical signatures (Crawford 1989; Falloon & Crawford 1991). However, more recent investigations have shown that boninites are not solely found in fore-arc but also in back-arc environments (Falloon *et al.* 1992; Deschamps & Lallemand 2003; Teklay 2006). In any case the SSZ nature of magmatism is well established (e.g., Topuz *et al.* 2014). The intra-oceanic subduction is also evidenced by oceanic crust rocks metamorphosed in the eclogite facies, of similar age as the SSZ ophiolites, dated at 172 ± 4 Ma by $^{40}Ar/^{39}Ar$ on phengite and by U-Pb on rutile in the Refahiye area (Topuz *et al.* 2013). In this scenario, the volcanic arc of this subduction would have then been either accreted to the Pontides margin (to the north) or subducted under it. There is yet no convincing evidence for any intra-oceanic arc to the north of the ophiolites. To the north of the Tethys oceanic domain the only arc during the Middle Jurassic to Late Cretaceous is the Pontides and Somkheto-Karabakh, which was bounded to the south by the north dipping subduction of Tethys.

Locally, Rice *et al.* (2009) show the presence of an intra-oceanic arc in the Karadağ ophiolites. However this formation is dated to the Late Cretaceous, and the authors suggest 'possibly because the lower part of the arc was detached and subducted'. However, some Upper Cretaceous calc-alkaline arc lavas are also found above an unconformity on top of Stepanavan ophiolites (Galoyan et al., 2007), just east of Karadağ ophiolites thus this arc may start in the Middle Cretaceous during of after the ophiolite obduction.

Consequently, when considering an intra-oceanic subduction model for the origin of Jurassic slow-spreading ophiolites, observations lead to conclude that the corresponding volcanic arc is missing. However, this observation may be tempered by the presence of volcanic arc remains in the ophiolitic sole lithologies / underthrusted 'mélange' unit (see dedicated following paragraph below). Determining whether ophiolites are of fore- or back-arc origin is not simple because of intricate obduction initiation as well as syn- and post-obduction processes. Both scenarios, fore- or back-arc origin, suggest the existence of an intra-oceanic arc. The structural and geochemical processes leading to their formation are almost identical, except for less important subduction contamination for back-arc tholeiites.

1.2.2.2 **Alkaline geochemical signatures**

Pillow-basalts with an Ocean Island Basalt (OIB) alkaline composition lie on top of the ophiolite series in Armenia (Galoyan *et al.* 2007, 2009; Galoyan 2008; Rolland *et al.* 2009, 2010; Hässig et al., 2013), and in NE Turkey as well (e.g., Parlak et al., GSL, and Hässig et al., 2014 for a review). These alkaline rocks are thus not related to the generation of the SSZ-type oceanic crust. They are found directly above an unconformity on top of the ophiolite body in Armenia, outcropping as fresh and large (meter-scale) pillow lavas embedded in pelagic limestones, dated at 117 Ma (mid-Early Cretaceous) by Ar-Ar on amphibole by Rolland *et al.* (2009), confirmed by radiolarian biostratigraphy (Danelian *et al.* 2012). Such occurrences of volcanism are widespread, though of variable thickness, in the various ophiolite locations. They are also described within the Karabagh and Amasia areas where late Barremian to early Aptian (~113 Ma; Asatryan *et al.* 2011) and Cenomanian (96~92 Ma; Danelian *et al.* 2014) radiolarians, respectively, bracket this submarine volcanism. Along the Sevan-Akera segment of the suture zone, between the Amasia and Karabagh zones, the Sevan ophiolite exhibits latest Tithonian to late Valanginian (135~123 Ma) radiolarians intercalated with mafic volcanic rocks (Asatryan *et al.* 2012). These datings evidence a long lasting volcanic activity from the end of the Jurassic, throughout the Early Cretaceous and up to the beginning of the Late Cretaceous not linked with the generation of the SSZ type oceanic crust. Compilations made by Moix & Goričan (2013) also show such occurrences of volcanism bracketed by Late Jurassic and Cretaceous radiolarians along the Izmir-Ankara-Erzincan segment of the northern tethyan suture zone (**Figure 58**).

The widespread occurrence of these rocks however suggests other magmatic processes than just a punctual and long-lived feature hot-spot, which may not be disconnected to subduction s.l.

Figure 58 - Compilation of chronological data including extension of the radiolarian fauna, magmatic series of the ophiolite bodies outcropping emplaced prior to the obduction event and metamorphic lithologies marking the limit between the ophiolites and the Eurasian margin as well as between the ophiolites and the underthrusted EAP-SAB margin from the İzmir-Ankara-Erzincan and Sevan-Akera sutures including the Bornova Zone and the Karaburun Peninsula, modified after Moix & Goričan (2013). The evolution of the various geological contexts between the Eurasian margin and the EAP-SAB is further argued by both biostratigrapghic and radiochronologic data. The red lines underline the emplacement of OIB type volcanism on the oceanic crust to be obducted. Locations are numbered and plotted on Figure 57: (1) Çakmakoğlu & Bilgin (2006); (2) Tekin & Göncüoğlu (2009); (3) Tekin *et al.* (2006) in Göncüoğlu *et al.* (2006a); (5) Tekin & Göncüoğlu (2007) and Tekin & Göncüoğlu (2008); (4) Tekin *et al.* (2012a); (10) Göncüoğlu *et al.* (2000); (7) Göncüoğlu *et al.* (2006b); (8) Göncüoğlu *et al.* (2006b); (9) Tekin *et al.* (2002) and Göncüoğlu *et al.* (2006a, 2010); (6) Servais (1982); (11) Bragin & Tekin (1996); (12) Rojay *et al.* (2004); (13) Çelik (2010) and Üner (2010) in Tekin *et al.* (2012b); (14) Tüysüz & Tekin (2007); (15) Boccaletti *et al.* (1966); (16) Bozkurt *et al.* (1997); (17) Hässig *et al.* (2013, 2014) and Danelian *et al.* (2014); (18) Danelian *et al.* (2008, 2012) and Rolland *et al.* (2010); (19) Galoyan *et al.* (2009) and Asatryan *et al.* (2010, 2012). Plots for magmatic rocks between (16) and (17) are for the Refahiye ophiolite from Topuz *et al.* (2013a, b) as for metamorphic rocks along with Aslan *et al.* (2011). Plots for metamorphic rocks between (17) and (18) are for the Stepanavan ophiolite from Rolland *et al.* (2009a).

1.2.3 The 'mélange' unit(s)

The mélanges found under the ophiolitic units represent (1) a sedimentary mélange represented by dismembered pieces of the thrusted ophiolites that fell in the obduction frontal basin (Huene *et al.* 2004; Vannucchi *et al.* 2008; Festa *et al.* 2010), as well as (2) tectonic mélanges, represented by scraped off features of the underthrusted units, tectonically intercalated with overthrusting ophiolite unit (Cloos & Shreve 1988; Dilek & Whitney 1997; Elitok & Drüppel 2008). The geochemical composition of part of the metamorphic units beneath the Stepanavan, Amasia and Hınıs ophiolites shows a distinct alkaline affinity similar to the alkaline oceanic island basalts (OIB) suite emplaced on top of the ophiolite. This lithological blend was then overthrusted by the ophiolitic unit and incorporated and metamorphosed throughout thrusting with other metamorphics beneath the ophiolites as described by Engi *et al.* (2001).

In the Erzincan area, previous works as well as field observations evidence the presence of a dismembered thrust sheet of marbles containing Permian foraminifers (fusulinids; Özgül 1981) topping highly schistosed low-grade metamorphosed magmatic rocks, directly beneath the obduction contact. These marbles could represent mega-lenses or mega-olistoliths emplaced through tectonic transport between the overthrusted upper ophiolite unit and the Tauride-Anatolide Platform unit (TAP).

1.2.3.1 Metamorphic rocks underneath the ophiolite

The metamorphic rocks below the obduction contact were originally emplaced anywhere between the SAB passive continental margin to the south and the future-obducted ophiolite in SSZ position to the north. These rocks underwent a severe deformation featured

by a penetrative schistosity, shear planes and rolling structures (snowball garnets) in a simple shear strain regime, ascribed to the ophiolite emplacement (Hässig *et al.* in review). To the north of the Erzincan Basin, the basal contact of this unit is shielded by Cenozoic deposits rendering it difficult to relate this unit to an intra-oceanic or to a continental environment (the Taurides block). Analyses of these Erzincan metamorphic rocks, phyllites with calc-alkaline affinities, are documented by Gücer *et al.* (2007). Their geochemistry testifies of meta-basalts with tholeiitic to calc-alkaline tendencies compatible with a volcanic arc environment. Even if there is no yet any convincing geochronological data to bracket the original emplacement of these rock types before obduction, the presence of these rocks argues for the occurrence of a volcanic arc between the passive continental margin to the south and the future ophiolites to the north, prior to obduction. This further argues for an intra-oceanic subduction, which accounts for the creation of oceanic crust in a supra-subduction setting.

Also recent $^{40}Ar/^{39}Ar$ ages have been calculated by Aslan *et al.* (2011) for plagioclases populations, which yield ages of 94.1 ± 3.3 and 60.7 ± 4.9 Ma for the metamorphism of this unit. Let us point out that these ages are globally similar to those of the Stepanavan metamorphic unit along the Sevan-Akera suture zone (blueschists dated at 95~91 and partially reset in greenschist facies at 71 Ma; Rolland *et al.* 2009).

1.2.4 The underthrusted continental domains (EAP-SAB)

The East Anatolian Platform (EAP) is prolonged by the SAB to the East. This domain represents a continental platform between the northern and southern branches of Neotethys (Bozkurt & Mittwede 2001). The EAP-SAB represents a sliver of a small continental plate having drifted off northern Gondwana towards the north, and then collided with Eurasia (Stocklin 1974; Adamia *et al.* 1977; Biju-Duval *et al.* 1977; Stöcklin & Bhattarai 1977; Dercourt *et al.* 1986; Şengün 2006; Barrier & Vrielynck 2008; Sosson *et al.* 2010). Palaeomagnetic analyses indicate palaeo-latitudes for the EAP-SAB during the Early and Middle Jurassic at least 2000 km farther south than its current position (Bazhenov *et al.* 1996; Meijers *et al.* 2013). This argues for a Gondwanian origin of the EAP-SAB, as also suggested by the dating undergone by Baghdasarian & Ghukasian (1983) and palaeogeographic reconstructions (Knipper & Khain 1980; Monin & Zonenshain 1987; Şengör *et al.* 1988; Robertson & Mountrakis 2006; Barrier & Vrielynck 2008). The rifting of the Taurides-Anatolides (including the SAB) from Gondwana is documented as initiating during Triassic times (Mart 1987; Gealey 1988; Kazmin 1991).

1.3 Discussion: what evolution of the geodynamic processes can explain the pre-obduction framework?

Throughout the Mesozoic and Cenozoic, the northern margin of the SAB-TAP, as well as the southern Eurasian margin, were involved in subduction and accretion/collision processes resulting in closure of the northern branch of the Tethys ocean (Adamia *et al.* 1981, 2011; Şengör & Yılmaz 1981; Dercourt *et al.* 1986; Zakariadze *et al.* 1990, 2005; Ricou 1994; Nikishin *et al.* 1998; Yilmaz *et al.* 2000; Stampfi *et al.* 2001; Robertson 2002; Golonka 2004; Galoyan 2008, 2009; Rolland *et al.* 2009a, b, 2010, 2011, 2012; Sosson *et al.* 2010; Hässig *et al.* 2013, 2014; Topuz *et al.* 2013).

Before obduction, paleomagnetic studies have shown that during Early-Middle Jurassic times the SAB-TAP was at least 2000 km south of the Eurasian margin (Bazhenov *et al.* 1996; Meijers *et al.* 2013).

After the NE Anatolian-Lesser Caucasus obduction event, during the Late Cretaceous, an oceanic domain still subsisted between the obducted ophiolite nappe and the Eurasian margin farther north. Paleomagnetic analyses indicate that a maximum of 1200~1000 km of oceanic lithosphere still separated the two continental domains during the Santonian, but the 40° rotation inferred from paleo-declinations suggest a significant rotation that may be ascribed to a highly dissymmetrical oceanic basin (Meijers *et al.* 2013). This ocean totally closed 20 Ma later as testified by the setup of a foreland basin on the obduction front and uplift and erosion along the suture zone. This continental collision event is clearly indicated by the Late-Middle Eocene unconformity on the SAB, the suture zone and the Eurasian margin, but the start of the collision occurred in the Latest Cretaceous. Then collision evolved and the domain was deformed from late-Middle Eocene to Miocene by thrusts and reverse faults (Galoyan *et al.* 2007; Rolland et al. 2009a; Sosson *et al.* 2010).

Geological data indicate that, within a convergent system, obduction occurred as the penultimate process, possibly by accommodating a slowing in subduction under the Eurasian margin, before continental collision, which may be due to underthrusting of seamounts, a thick oceanic plateau or the back-arc ridge. In order to illustrate how obduction is possible, we propose the following geodynamic reconstruction (**Figure 59**).

1.3.1 Geodynamic reconstruction

1.3.1.1 North-dipping Northern Tethys subduction under Eurasia

The north-dipping subduction of the Tethyan oceanic domain under the southern Eurasian margin ranges from Middle Jurassic to middle-Late Cretaceous times (c. 170-83 Ma). It is evidenced in the Eastern Pontides and Somkheto-Karabakh regions of the Lesser Caucasus. They correspond during this time interval to a continental magmatic arc. This is testified by occurrences of granodiorite and tonalite intrusions mainly dated to Middle Jurassic times (Sengör & Yilmaz 1981), cross cutting a crystalline basement metamorphosed in the Carboniferous (340-330 Ma, e.g., Topüz, Treloar) and covered by Upper Paleozoic to Lower Jurassic sediments (Adamia et al., 1981). Calc-alkaline volcanism is continuous throughout the Middle to Late Jurassic, even though diminishing on through to the beginning of the Late Cretaceous marked alternations with relatively deep-water sediments (Kazmin *et al.* 1986). It is noteworthy that the diminishing in volcanic arc activity broadly coincides with the onset of obduction on EAP-SAB. This subduction related volcanism is reported as intensive along the southern margin of Eurasia later during Late Cretaceous times (Sengör & Yilmaz 1981), which argues for a regained subduction just after the short-lived obduction (90-86 Ma). Volcanic arc lithologies related to subduction are exposed in the southern Pontides Arc (Adamia *et al.* 1977, 1981; Ustaömer & Robertson 1995; Rice *et al.* 2009; Dilek *et al.* 2010). This suggests that the eastern Pontides developed by northward subduction of remaining Palaeotethys and juvenile Neotethys at least from Jurassic to Late Cretaceous times (Adamia *et al.* 1981; Yilmaz *et al.* 2000).

1.3.1.2 The Supra-subduction zone to back-arc domain

An intra-oceanic subduction zone is evidenced by the preserved non-metamorphic obducted oceanic crust, the ophiolitic nappe. This oceanic crust formed in a supra-subduction to a back-arc basin setting ascribed to subducting slab roll-back. This north-dipping intra-oceanic subduction, north of the SAB, is accountable for Early Jurassic to middle-Early Cretaceous ages obtained for ophiolite lithologies (gabbros and basalts) (Aghamalyan 1998; Galoyan 2008; Rolland *et al.* 2009b, 2011; Hässig *et al.* 2013). The north-dipping of this structure is also argued by the overall geometry of the tectonic pile, as by that of the outcrops of low-grade metamorphics, blueschist and amphibolite facies rocks below the ophiolite nappe along the Ankara-Erzincan and Sevan-Akera suture zones in the Refahiye (Aslan *et al.* 2011), Stepanavan (Rolland *et al.* 2009a; Sosson *et al.* 2010) and Amasia areas (Hässig *et al.* 2013), respectively. This intra-oceanic subduction zone is considered to be synchronous with subduction under Eurasia farther north because ages obtained for the ophiolite units (gabbros and basalts) are encompassed within those of volcanism along the southern margin of Eurasia. The timing of peak metamorphism for the metamorphic units (c. 97~91 c. 95~91 Ma and c. 92~88 Ma) is considered to mark the onset of the obduction process, thus timing of the proposed pre-obduction setup.

Radiometric datings of ophiolitic lithologies are supported by occurrences of radiolarites interbedded with volcanic layers of basaltic lava flows and tuffs, representing the upper most part of the ophiolite sequence. These radiolarites yield continuous biochronologic ages either form Early Jurassic or Middle Jurassic to early-Late Cretaceous times (e.g. Danelian *et al.* 2014; **Figure 58**). We consider the Triassic radiolarian ages, either from blocks of the mélange or from the upper parts of the ophiolite's tectonic pile, to be relics of the oceanic crust that partly disappeared in the northern subduction zone.

Throughout the evolution of the future ophiolite body, from genesis to the onset of obduction, radiochronology as well as radiolarites may be used also to temporally bracket the emplacement of sediments or volcanic rocks. Occurrences of Ocean Island Basalts (OIB) have been identified dating back to the Middle Jurassic (Tekin *et al.* 2006; Tekin & Göncüoğlu 2009) but mainly spanning from Early and early-Late Cretaceous times (Aptian and Cenomanian; Rolland *et al.* 2010; Danelian *et al.* 2014). Similar Cretaceous alkaline series are also found above the Iranian ophiolites, in the region of Khoy (Ghazi & Hassanipak, 1999; Avagyan et al. this volume). Even if it is still difficult to relate these alkaline events to one another due to their geographical and temporal distribution, it is most likely from their

geochemistry that their emplacement is linked with upwelling of hot mantle material ('plumes'; e.g. Rolland *et al.* 2009b; Parlak *et al.* 2013). We believe that this last observation may be an important factor towards solving the obduction paradox, that is to say a continental domain overthrusted by an old yet hot oceanic lithosphere. Indeed, widespread plume activity is evidenced by alkaline volcanism within 20 Ma before the obduction (Bektaş etal. 1999; Çelik 2007 Rolland *et al.* 2009b; Danelian et al. 2014). The widespread character of this event has thus potentially resulted in a significant decrease in Ocean Lithosphere thickness,density, and has produced an increase of its buoyancy..

1.3.1.3 An active or passive northern SAB-TAP TOC margin?

During the Late Jurassic and Early Cretaceous times structural, geochronological and petrological observations have shown a multiphase evolution of the northern margin of the SAB (Hässig *et al.* in review). A south-dipping subduction under the EAP-SAB is implemented to the model in order to suit recent findings pertaining emplacement of relatively hot subduction related granodiorite as well as the metamorphic evolution of the crystalline basement in the Lesser Caucasus area (Hässig *et al.* in review). The metamorphism is interpreted as evidencing: (1) M1 Barrovian MP-MT conditions (staurolite-kyanite) at c. 157-160 Ma and intrusion of dioritic magmas at c. 150-156 Ma, (2) near-adiabatic decompression is featured by partial melting and production of leucogranites at c. 153 Ma, followed by M2 HT-BP conditions (andalusite - K-feldspar). A phase of shearing and recrystallization is ascribed to doming at c. 130-150 Ma and cooling at 400°C by c. 123 Ma (M3). Structural observations show (1) top to the north shearing during M1 and (2) radial extension during M2.

Existence of this structure along the entire northern EAP-SAB margin is uncertain because of the lack of outcrops of basement rocks under the ophiolite nappe (**Figure 56**) and of geochronological data in NE Turkey. Accordingly, we propose two alternatives for the evolution of this zone marking the transition between ocean and continental domains (TOC), whether as a passive margin (**Figure 59A**) or as an active margin (**Figure 59B**), as this zone may still represent a local feature on the northwards drifting EAP-SAB.

1.3.1.3.1 Passive TOC margin

In the first case, a passive TOC margin, the intra-oceanic subduction retreats until the arrival of the EAP-SAB into the subduction. In this configuration, the north-dipping

subduction of the passive TOC provides a favorable pre-structure for later passive obduction (**Figure 59**). A similar context is described for the formation of the Antler orogen along an E-W cross-section from central California to central Utah in the United States between Middle Devonian and Late Devonian~Early Mississippian times (Speed & Sleep 1982; Ingersoll 1997, 2008; Dickinson 2000). In this model, as in ours, a relatively hot SSZ is overthrusted onto the subducting passive continental margin. This passive margin does not subduct farther than 45~25 km representing pressures between 15 and 7 kbar. Shortly following the entrance of this passive TOC into the subduction zone, shallow detachment or break-off is suggested by the end of subduction related volcanism in the overriding plate at this time.

Zedde & Wortel (2001) investigate the modalities of shallow oceanic slab detachment upon arrival of a continental slab in a subduction zone. This study concludes that depth of break-off is dependent of the thermal state of the passive TOC. This deduction is supported by numerical modelling (Duretz & Gerya 2013) showing that break-off depth is related to the coupling of the strength and the forces acting on the passive TOC, strength which is itself dependent of the rheology and thermal state of the TOC. In the scenario where the TOC margin is passive a shallow breakoff is implied, in order to fit the geological data showing only low degrees of metamorphism for the continental EAP-SAB: absence of eclogites, reset of paleomagnetic markers suggesting 200<T<400°C (Meijers et al., in review).

1.3.1.3.2 **Active TOC margin**

In the alternate possibility, an active TOC margin, the south-dipping and north-dipping intra-oceanic subductions configure a double divergent subduction setting. This framework is constituted by the EAP-SAB to the south and the future ophiolite to the north as the converging overriding plates. Models featuring divergent double subduction systems for the formation of orogens are rather rare. Still, in Thailand (Hutchison 1989), the Philippine arc (McKenzie 1969), the Nevadan belt in Western USA (Ingersoll 2008) and the Lachlan fold belt in southeastern Australia (Soesoo *et al.* 1997; Gray *et al.* 2002) such a context has been proposed.

Throughout the evolution of the two opposite convergent margins, the oceanic domain caught between the two gradually shortens. Ingersoll (2008) shows that in such a context the oceanic active margin is thrusted onto the continental active margin while the subducting intermediate portion sinks into the mantle. The entire system is unlikely to be perfectly symmetric and thus sinking will probably initiate from one side and propagate towards the

other side. As this central portion sinks, upward mantle flow has to fill the resulting gag. Decompressional melting of mantle wedge material ought to result as a response to asthenosphere uplift and tectonic underpressure due to the sinking oceanic lithosphere pulling on the overriding plates.

In the scenario comprised of an active TOC margin bordering the north of the EAP-SAB continental block, the sudden and rapid heating and melting at the base of the active overriding oceanic margin to the north is thus arguable. In the resulting setup, the former active margin of the future ophiolite overrides the continental margin towards the south. It is reasonable to propose that the occurrences of volcanism throughout Early Cretaceous times, emplaced in an oceanic environment prior to obduction, partly represents manifestations of this heating. Thus, the section of oceanic lithosphere to be obducted, just prior emplacement, is 50~80 Ma old but rather hot because of mantle flows inducted by the sinking of the divergent double subducting oceanic crust.

1.4 Conclusion

A model concerning the evolution of the northern Neotethys is argued on the base of the structural, geochemical and geochronological studies pertaining to preserved oceanic crust domains (ophiolites) obducted as in the Lesser Caucasus and in NE Anatolia and of the metamorphic rocks beneath these ophiolites. These studies provide constraints into the evolution of the Tethyan realm. As a result of this review, a geologic setup for future investigations and numerical modeling is proposed (**Figure 59**):

1- The magmatic and ultrabasic rocks composing the ophiolitic nappe originate from a SSZ basin that slowly opened in a preexisting ocean domain, While this domain subducted under Eurasia farther north. We thus infer the existence of an intra-oceanic subduction at this time and a probable rollback of the intra-oceanic subduction slab as a motor for this spreading. Radiometric dating and biostratigraphy allow us to confine this first snapshot in the Early Jurassic to Early Cretaceous times (**Figures 59-1**, **59-2** & **59-3**).

2- Recent investigations evidence subduction under the northern margin of the SAB-EAP with emplacement of granodiorite intrusions during the early-Late Jurassic (c. 160 Ma). The western continuity of this structure into NE Anatolia is uncertain, thus we present from this point on two alternate models, one without a

south-dipping subduction and another with (**Figures 59-2A** & **59-2B**, respectively and so forth).

3- In nearly all ophiolite outcrops, two magmatic suites are evidenced one on top of the other: (1) oceanic crust topped by (2) basaltic flows or volcanic tuff with alkaline tendencies. Radiochronology and biostratigraphy both show that emplacement of this second suite occurs in an ocean environment prior to ophiolite emplacement throughout Middle to Late Jurassic and even until early-Late Cretaceous times. Geochemical analyses tend to validate the hypothesis of mantle originating hot-spot type "plumes".

4- In our scenarios (**Figures 59-4A** & **59-4B**), the intra-oceanic subduction retreats to the northern SAB-EAP margin. Since no high pressure metamorphism is evidenced in the rare outcrops of the SAB-EAP crystalline basement, this illustrates either (1) early slab breakoff or (2) intermediate slab sinking due to divergent double subduction slab rollback, respectively in the case of a passive or active north SAB-EAP margin (**Figures 59-5A** & **59-5B**). The resulting setup shows a favorable geometry for oceanic crust thrusting onto the SAB-EAP.

5- The absence of the volcanic arc formed above the intra-oceanic subduction may be explained by its dragging under the obducting ophiolite through scaling, faulting and tectonic erosion. It is hypothesized that the low-grade metamorphics of Erzincan and blueschists of Stepanavan correspond to this missing volcanic.

6- Data indicate that the oceanic domain was still subducting under Eurasia after ophiolite emplacement (**Figure 59-7**). Reconstructions of the ophiolitic nappe account for 200 km of overthrusting from the present suture zone to Khoy (Iran) hypothesized to represent the most distal obduction front. The olistostrome yields a lower chronological limite to this obduction to Coniasian - Santonian times (c. 90~86 Ma). This observation is coherent with metamorphic ages for Erzincan low-grade metamorphic unit, the Amasia garnet amphibolites and the Stepanavan blueschists.

In order to explain such an obduction event, we believe the oceanic crust thrusted in the proposed pre-obduction setup (**Figure 59-6**) must be particularly hot. The heating of the oceanic lithosphere would be due to important upwelling mantle flows, evidenced by the alkaline volcanism on the ophiolite, thus altering its rheological properties.

Acknowlegements

Chapitre 6 - Mise en place d'ophiolites préservées : une modélisation.

« Pour atteindre la vérité, il faut une fois dans la vie se défaire de toutes les opinions qu'on a reçues, et reconstruire de nouveau tout le système de ses connaissances. »

René Descartes

Dans cette partie nous présentons une modélisation intégrant les caractéristiques générales du domaine océanique maintenant disparu dont les ophiolites sont les seules reliques. La reconstitution géodynamique proposée avant l'obduction des ophiolites du Petit Caucase-NE Anatolie nous a permis de déterminer une structuration de la transition océan-continent (TOC) entre le SAB-TAP et la branche nord de la Néotéthys. Grace à une collaboration avec ***Thibault DURETZ*** *(Université de Lausanne), nous avons pu tester certaines hypothèses grâce à des modèles numériques thermo-mécaniques 2D. Ces modèles ont confirmé l'hypothèse principale que la lithosphère océanique devait être particulièrement chaude avant l'obduction. Cet état thermique anormalement élevé provoquerait un affaiblissement de la lithosphère facilitant le processus d'obduction. Les données géologiques fournissent des contraintes spatiales et temporelles afin de valider ou réfuter ce scénario. En replaçant cet évènement d'obduction dans le cadre de la convergence Arabie-Eurasie, nous évoquerons également d'autres hypothèses qui découlent de cette modélisation (i.e. interaction avec la subduction au nord sous l'Eurasie, résultats de datations perturbées…). En conséquence, une discussion des processus à l'origine de l'obduction est proposée pour expliquer le cas d'étude et plus généralement le mécanisme d'obduction.*

VI.1 Introduction

Les études précédentes présentées dans ce mémoire ont mis en évidence les liens entre les massifs ophiolitiques des régions du Petit Caucase et du NE de l'Anatolie. Des structures géologiques semblables, des âges identiques et des compositions géochimiques semblables vérifiées en différents points de cet ensemble ophiolitique, suggèrent qu'il s'agit d'un domaine océanique continu, d'est en ouest, séparant la marge eurasienne de celle du SAB-TAP jusqu'à la fin du Mésozoïque (voir chapitre III.1), passé en obduction sur celle-ci entre 94 et 85 Ma. La continuité de ce domaine est soutenue par des âges identiques obtenus par différentes méthodes géochronologiques ($^{40}Ar/^{39}Ar$ et U-Pb) et biochronologique (radiolaires). Elle est confirmée par des affinités et des tendances géochimiques analogues obtenues lors de comparaisons d'analyses pétrogéochimiques, montrant 2 séries magmatiques superposées d'âge distinct (voir chapitres III et IV). Un contexte de formation en SSZ à arrière-arc par ouverture lente a été déduit concernant la formation du plancher océanique des ophiolites, entre le Jurassique inférieur et Crétacé inferieur (c.180~150 Ma) (voir chapitres III et IV). La corrélation latérale de la discontinuité basale de l'obduction sur les sections lithostratigraphiques le long de la zone de suture d'Izmir-Ankara-Erzincan et Sevan-Akera à l'échelle du bloc SAB-TAP, a montré la mise en place quasi-simultanée de ces ensembles ophiolitiques au Turonien-Coniacien-Santonien (c. 94~85 Ma) (voir chapitre IV). Le métamorphisme des roches en position basale (la semelle ophiolitique) a été contraint à un intervalle de temps similaire par la datation $^{40}Ar/^{39}Ar$ des phengites et amphiboles des amphibolites à grenat (voir chapitre III.2). Il est important de remarquer que des indices sédimentaires et structuraux permettent d'affirmer qu'un bassin océanique subsistait suite à la mise en place des ophiolites et avant la collision continent–continent (voir chapitres IV et VI).

Les données paléomagnétiques indiquent qu'il était probablement dissymétrique ce qui peut expliquer un diachronisme latéral d'Est en Ouest (**Figure 60**).

En intégrant les témoins d'activité volcanique observée sur les deux marges continentales un modèle d'évolution a été proposé dans les chapitres précédents, se distinguant par une mise en place commune, telle une nappe, de l'ensemble de ces corps ophiolitiques (voir chapitres V et VI).

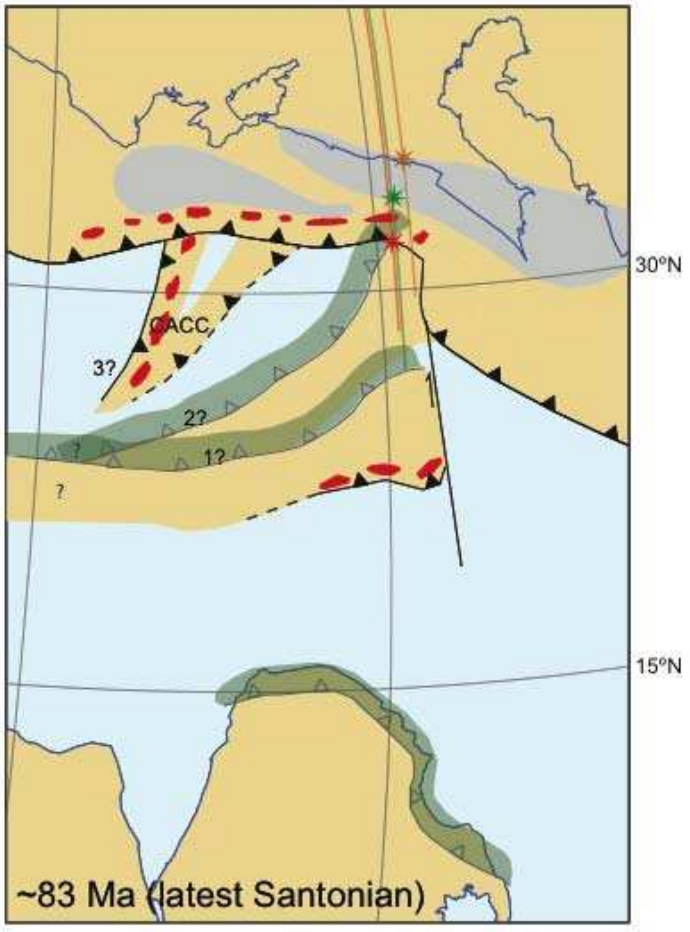

Figure 60 - Reconstitution du bloc TAP-SAB et des bassins océaniques environnants au Santonien, suite à l'obduction, d'après les données paléomagnétiques (Meijers et al., en révision). Les étoiles et marges d'erreur associées indiquent les paléo-latitudes des roches calcaires en discordance sur l'ophiolite obduite, mises en place juste après l'obduction). La position 1 décrit la position la plus méridionale et 2 la plus septentrionale du bloc TAP-SAB. L'obliquité du bloc est déduite d'une déclinaison de 40° impliquant une rotation de même valeur au moment de la fermeture de la branche nord de l'océan Téthys. La position 3 décrit la possibilité d'une zone de subduction très oblique, par rapport à la marge eurasienne, en bordure occidentale du bloc de Kirshehir (ou Central Anatolian Crystalline Complex, CACC, Lefebvre, 2011).

Dans la quasi-totalité des massifs ophiolitiques, deux suites magmatiques ont été mises en évidence l'un sur l'autre: (1) la croûte océanique surmontée de (2) coulées basaltiques ou tuf volcanique avec des tendances alcalines. Les datations radiochronologique ainsi que biostratigraphique montrent que la mise en place de cette deuxième suite se produit dans un environnement océanique l'obduction des ophiolites. Ces roches alcalines témoignent de flux mantelliques important jusqu'au début du Crétacé supérieur. Le réchauffement de la lithosphère océanique dû à ces importantes remontées de flux mantellique produirait un affaiblissement de la plaque. Cette dernière observation favorise l'hypothèse que la croûte océanique charriée doit être particulièrement chaude pour expliquer un tel événement obduction.

Afin de tester cette hypothèse, nous proposons d'effectuer, à partir de la configuration pré-obduction proposée (voir chapitre VI, **Figure 59**), une modélisation numérique thermo-mécanique. Cette démarche permettra de tester différents paramètres intervenant dans l'obduction, et de contraindre certaines grandeurs physiques se rapportant autant à la rhéologie de la lithosphère océanique obduite qu'aux mouvements relatifs de l'ensemble des structures tectoniques impliquées.

VI.2 Modélisation numérique

2.1 Configuration

Nous avons effectué des simulations à partir d'un modèle comprenant une marge continentale et un domaine océanique séparés par un niveau serpentineux (**Figure 61**). Les simulations ont été effectuées en utilisant le code thermomécanique I2VIS (Gerya & Yuen, 2003), description complète disponible dans Duretz et al. (2012). Chaque lithologie est caractérisée par une température et un état de contrainte dépendant de sa rhéologie visco-plastique, tels que listés dans le **Tableau 18**. Suivant la démarche de Gerya et al. (2004), les simulations intègrent l'effet de changement de phase sur la densité des matériaux en négligeant l'effet cinétique des réactions. La taille du domaine modélisé est de 4000 x 1400 km avec un maillage variable (1361 x 351) afin d'atteindre un espacement des mailles de 1 km dans la zone de collision. Une vitesse de convergence de 5 $cm.a^{-1}$ a été initialement imposée. Après 500 km de convergence atteint, la convergence a été désactivée et nous avons imposé de l'extension à une vitesse de 5 $cm.a^{-1}$. Toutes les limites du domaine de modélisation sont à glissement libre. Une couche d'une épaisseur de 20 km d'air visqueux (ρ_{air} = 0 $kg.m^{-3}$, η_{air} = 10^{18} Pa.s) a été utilisée afin de mimer les effets d'une surface libre et ainsi de permettre le développement topographique (Schmeling et al., 2008; Crameri et al., 2012).

Tableau 18 – Paramètres thermiques et rhéologique des lithologies utilisé lors des modélisations.

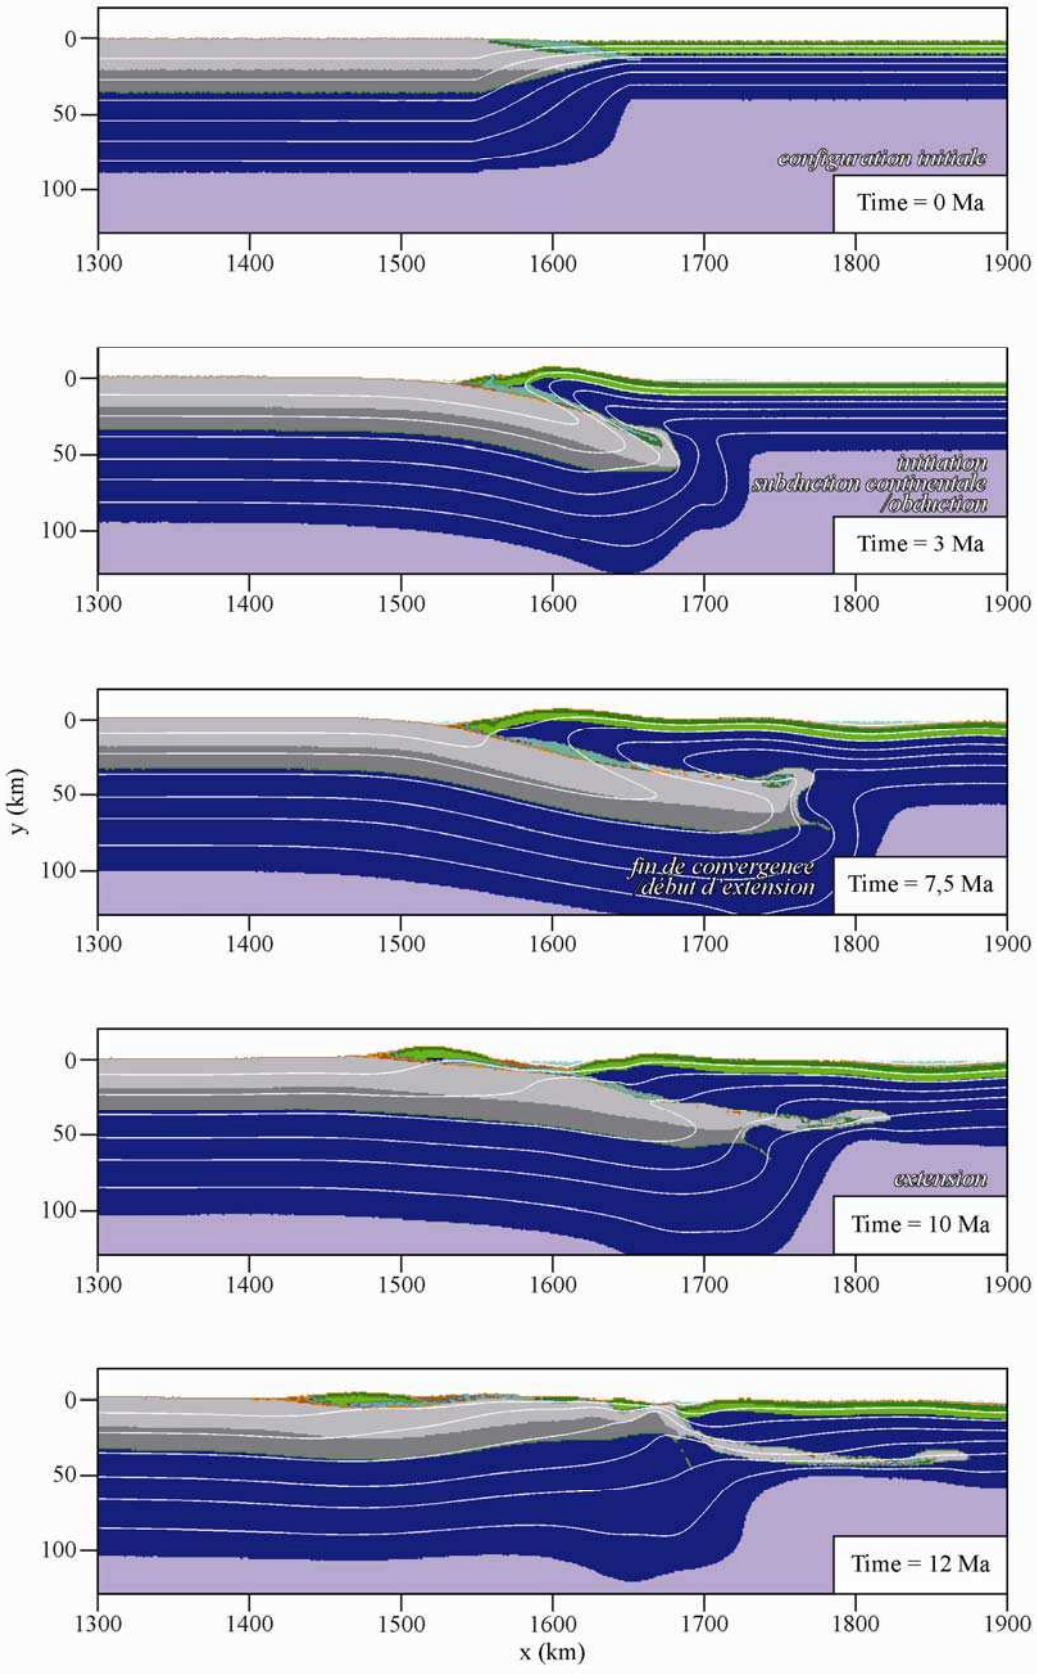
2.2 Modèle 1 - rajeunissement thermique étendu à tout le domaine océanique

L'évolution de ce modèle peut être décomposée en 2 étapes successives (**Figure 62**). La première étape est marquée par l'initiation d'une subduction continentale/obduction (chevauchement de lithosphère océanique sur de la lithosphère continentale ou le sous-charriage de cette dernière sous la première). Cette étape de forte compression horizontale est nécessaire pour expliquer des obductions simultanées en Oman (branche Téthys sud) et sur la branche Téthys nord. Nous avons indiqué que cette phase d'obduction s'accompagne également d'un ralentissement de la subduction sous la marge active de l'Eurasie au nord qui peut être causée par l'entrée en subduction de monts sous-marins, l'arrivée de la ride en subduction, ou encore le début de collision de l'extrêmité NE du bloc TAP-SAB (cf **Figure 60**). Par la suite, on constate une reprise de l'activité d'arc le long de la marge eurasienne. Dans cette modélisation nous avons donc imposé (1) une étape de compression où la subduction nord ne joue pas, (2) un arrêt de la compression et une reprise la subduction nord.

(1) Etape de compression

Lors de cette période les contraintes s'accumulent progressivement au cours de la convergence de deux domaines. La formation d'un bombement caractéristique d'un front de charriage se développe. La lithosphère océanique se retrouve ainsi charriée au-dessus de la lithosphère continentale. A 5 Ma la marge continentale en subduction atteint une profondeur à laquelle la flottabilité positive de sa croûte provoque une réduction de l'angle de plongement. A 6 Ma la subduction de la marge continentale progresse en une subduction plate avec un angle de plongement faible. La marge continentale est enfouie à une profondeur maximum de 50 km.

Figure 62 – Evolution temporelle du modèle 1 caractérisé par une lithosphère océanique vieille mais d'un âge thermique de 5 Ma sur la totalité de son étendu.



Le front de charriage est le résultat d'une zone de friction à l'interface entre les croûtes continentale et océanique. Cette friction entraîne l'érosion tectonique de la croûte océanique chevauchante et le sous-charriage de ces produits d'érosion dans le contact interplaque. Depuis l'initiation de la subduction continentale/obduction jusqu'à l'aplatissement du panneau plongeant à 6 Ma, un chenal de subduction/obduction se développe. Les sédiments et produits d'érosion sont entraînés à des profondeurs et des températures maximales de 35~40 km et 750 °C. Au cours de la formation du front de charriage, en arrière de celui-ci se forme un bassin de type 'piggy back' dans lequel s'accumulent également des sédiments.

A 7,5 Ma, les 500 km de convergence sont atteints. A ce stade la subduction continentale/obduction est terminée. Toutefois, une épaisseur non négligeable de lithosphère océanique a été charriée et mise en place (30~40 km). Or, les observations de terrain nous indiquent que les ophiolites représentent seulement une mince épaisseur de la partie crustrale de la lithosphère océanique (3~5 km). Nous ne retrouvons pas ou peu de manteau lithosphérique dans les massifs ophiolitiques.

(2) Reprise de la subduction nord

Dans la suite de la modélisation de l'extension est imposée. L'action combinée de cette traction imposée par la subduction nord sous la marge eurasienne et de la flottabilité positive de la croûte continentale subduite résultent en un amincissement vertical du système. Le manteau lithosphérique se retire sous l'effet de ces forces. L'alimentation du chenal de subduction/obduction est coupée. Les sédiments s'accumulent désormais en surface au contact inter-plaque. On constate que cette phase d'extension affecte en particulier la partie mantellique de l'ophiolite obduite. Au cours du retrait de la partie mantellique de la lithosphère océanique préalablement obduite, la partie crustale est découplée et déposée sur la lithosphère continentale. Le bombement du front d'obduction se réduit tout en s'élargissant en arrière de cette zone. Un bassin flexural se forme également en avant du bombement, reculant au fur et à mesure que la lithosphère se retire.

Au cours de cette délamination lithosphérique, des parties profondes du chenal de subduction/obduction sont exhumées sous l'effet de la remontée de la croute continentale. Ces roches métamorphiques se retrouvent ainsi en position basale de la croute océanique. Elles forment ainsi les écailles d'amphibolites à grenat identifiées dans 'la semelle ophiolitique'. Au regard de cette modélisation, nous suggérons que ces roches sont donc aussi des marqueurs d'un détachement de l'ophiolite que du passage en 'fer à repasser', en compression, de celle-ci. La zone de « Chenal d'obduction » ainsi exhumée enregistre ainsi les 2 étapes (obduction et retrait du manteau).

2.3 Modèle 2 - rajeunissement thermique du domaine océanique restreint à proximité de la marge continentale

L'évolution de ce modèle peut être décomposée en 2 étapes successives, les mêmes que pour le modèle précédent (**Figure 63**). Dans cette modélisation nous avons également imposé (1) une étape de compression où la subduction nord ne joue pas, (2) un arrêt de la compression et une reprise la subduction nord.

(1) Etape de compression

Au cours de la convergence de deux domaines les contraintes s'accumulent progressivement. Un bombement caractéristique d'un front de charriage se développe tout comme dans le modèle 1. La lithosphère océanique se retrouve ainsi charriée au-dessus de la lithosphère continentale. A 5 Ma la marge continentale en subduction atteint une profondeur à laquelle la flottabilité positive de sa croûte provoque une réduction de l'angle de plongement. Remarquons que cette profondeur est plus importante que celle constatée dans le modèle 1 dus à l'épaisseur plus importante de manteau lithosphérique la chevauchant. A 6 Ma la subduction de la marge continentale progresse en une subduction plate avec un angle de plongement faible. La marge continentale est enfouie à une profondeur maximum de 70 km.

Dans cette variante du modèle précédant, le front de charriage se forme selon les mêmes processus mais qu'il progresse plus loin sur le domaine continental. Le front de charriage est toujours le résultat d'une zone de friction à l'interface entre

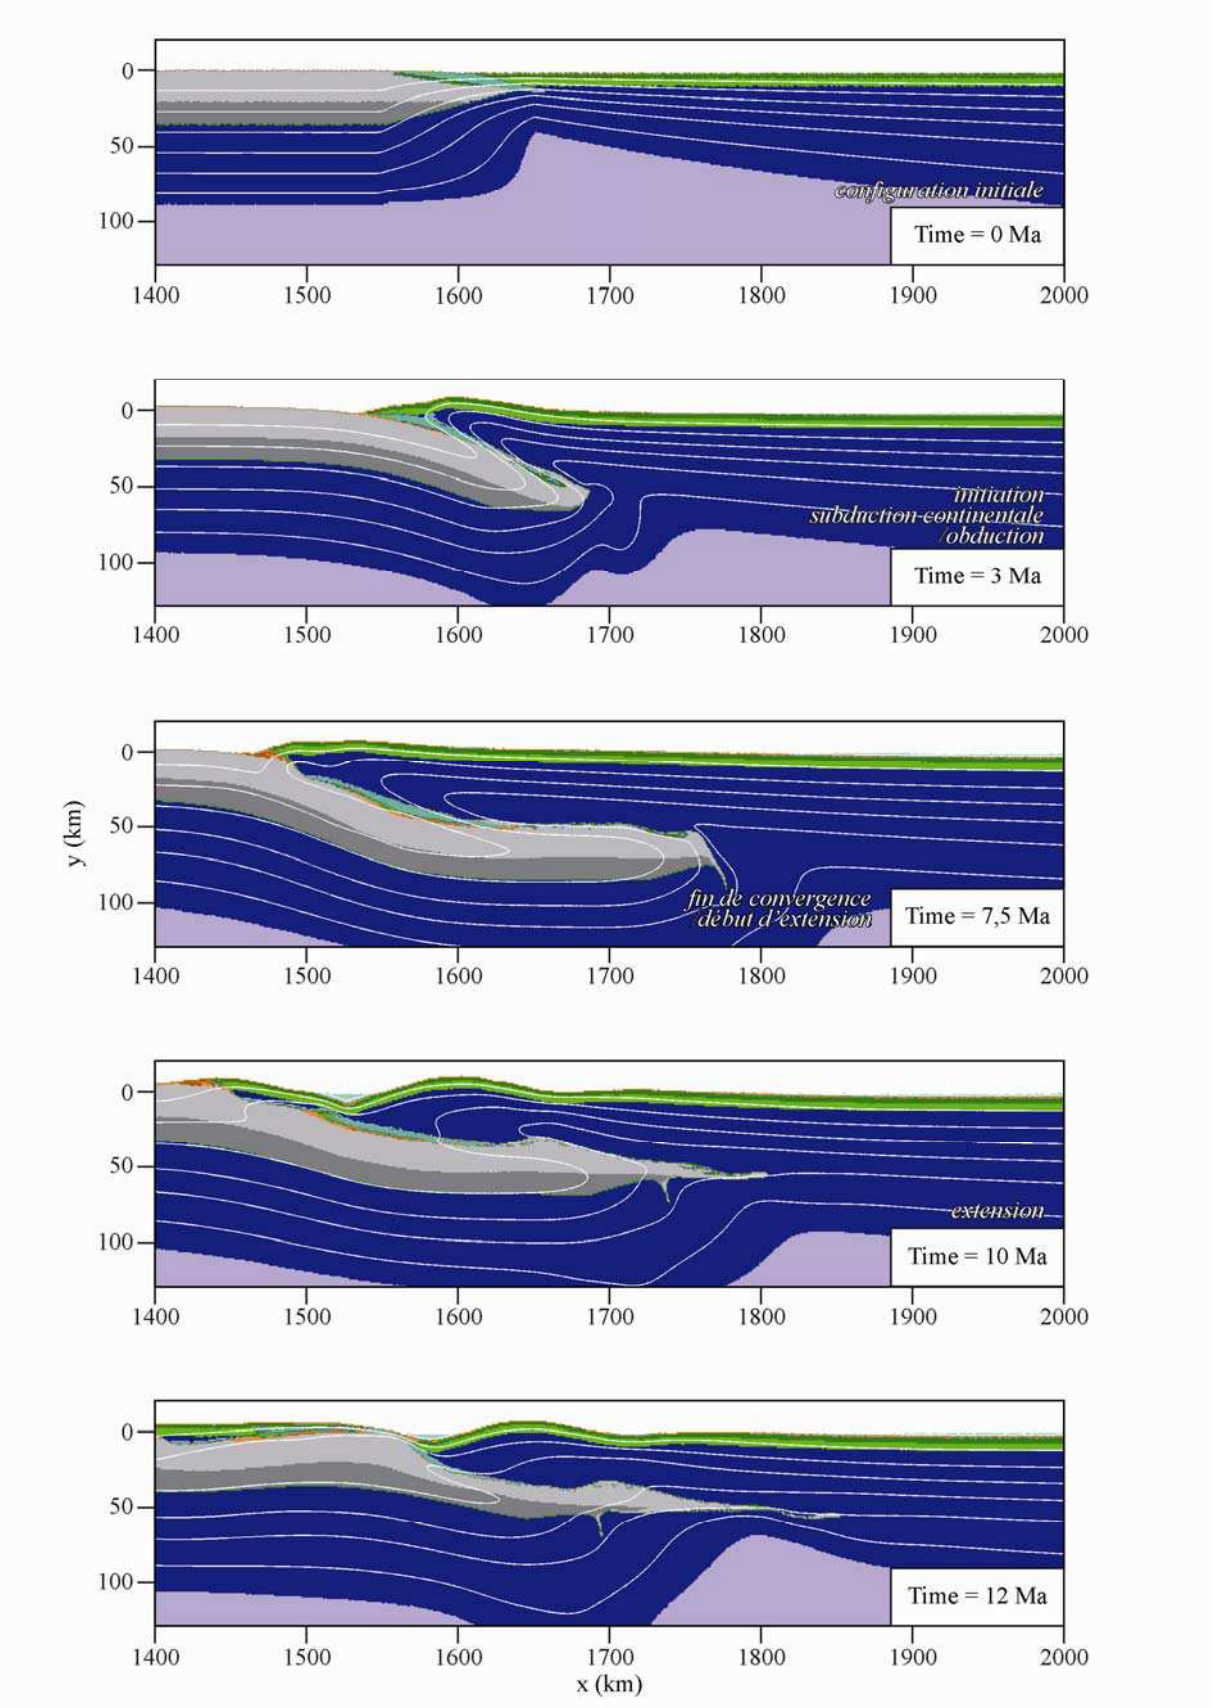
les croûtes continentale et océanique. L'érosion tectonique de la croûte océanique chevauchante et le sous-charriage de ces produits d'érosion dans le contact interplaque se produit de la même manière mais l'épaisseur de la lithosphère est plus importante en arrière de la zone de charriage. Depuis l'initiation de la subduction continentale/obduction jusqu'à l'aplatissement du panneau plongeant à 6 Ma, la propagation gravitaire de l'ophiolite est plus intense. Ainsi la formation un chenal de subduction/obduction se développe plus par effet de « fer à repassé » que par entrainement du panneau plongeant. Les sédiments et produits d'érosion sont entraînés à des profondeurs et des températures maximales de 50~60 km et 750 °C. Le bassin flexural qui se forme en avant du front de charriage présentent une profondeur plus importante que dans le modèle 1 alors que celui en arrière est moins marqué.

C'est également à 7,5 Ma que les 500 km de convergence sont atteints. Le stade subduction continentale/obduction s'arrête comme dans le modèle 1. Toutefois, une épaisseur encore plus importante de lithosphère océanique a été charriée et mise en place (~50 km).

(2) Reprise de la subduction nord

L'extension est imposée, comme dans le modèle 1. Cette traction a les mêmes effets que dans le précédent modèle. Remarquons toutefois qu'il subsiste une partie du manteau lithosphérique sous la croûte océanique malgré qu'il se retire sous l'effet des mêmes forces. On constate que cette phase d'extension affecte non seulement la partie mantellique de l'ophiolite obduite mais aussi la croûte continentale en subduction. Un bombement de la croûte continentale se développe, il sépare l'ophiolite du domaine océanique chevauchant l'extrémité de la marge continentale. Il est envisageable que l'obduction passive continue de faire progresser l'ophiolite sur le domaine continental.

Figure 63 - Evolution temporelle du modèle 2 caractérisé par une lithosphère océanique vieille mais d'un âge thermique de 5 Ma sur restreint à un domaine proche de la marge continentale.



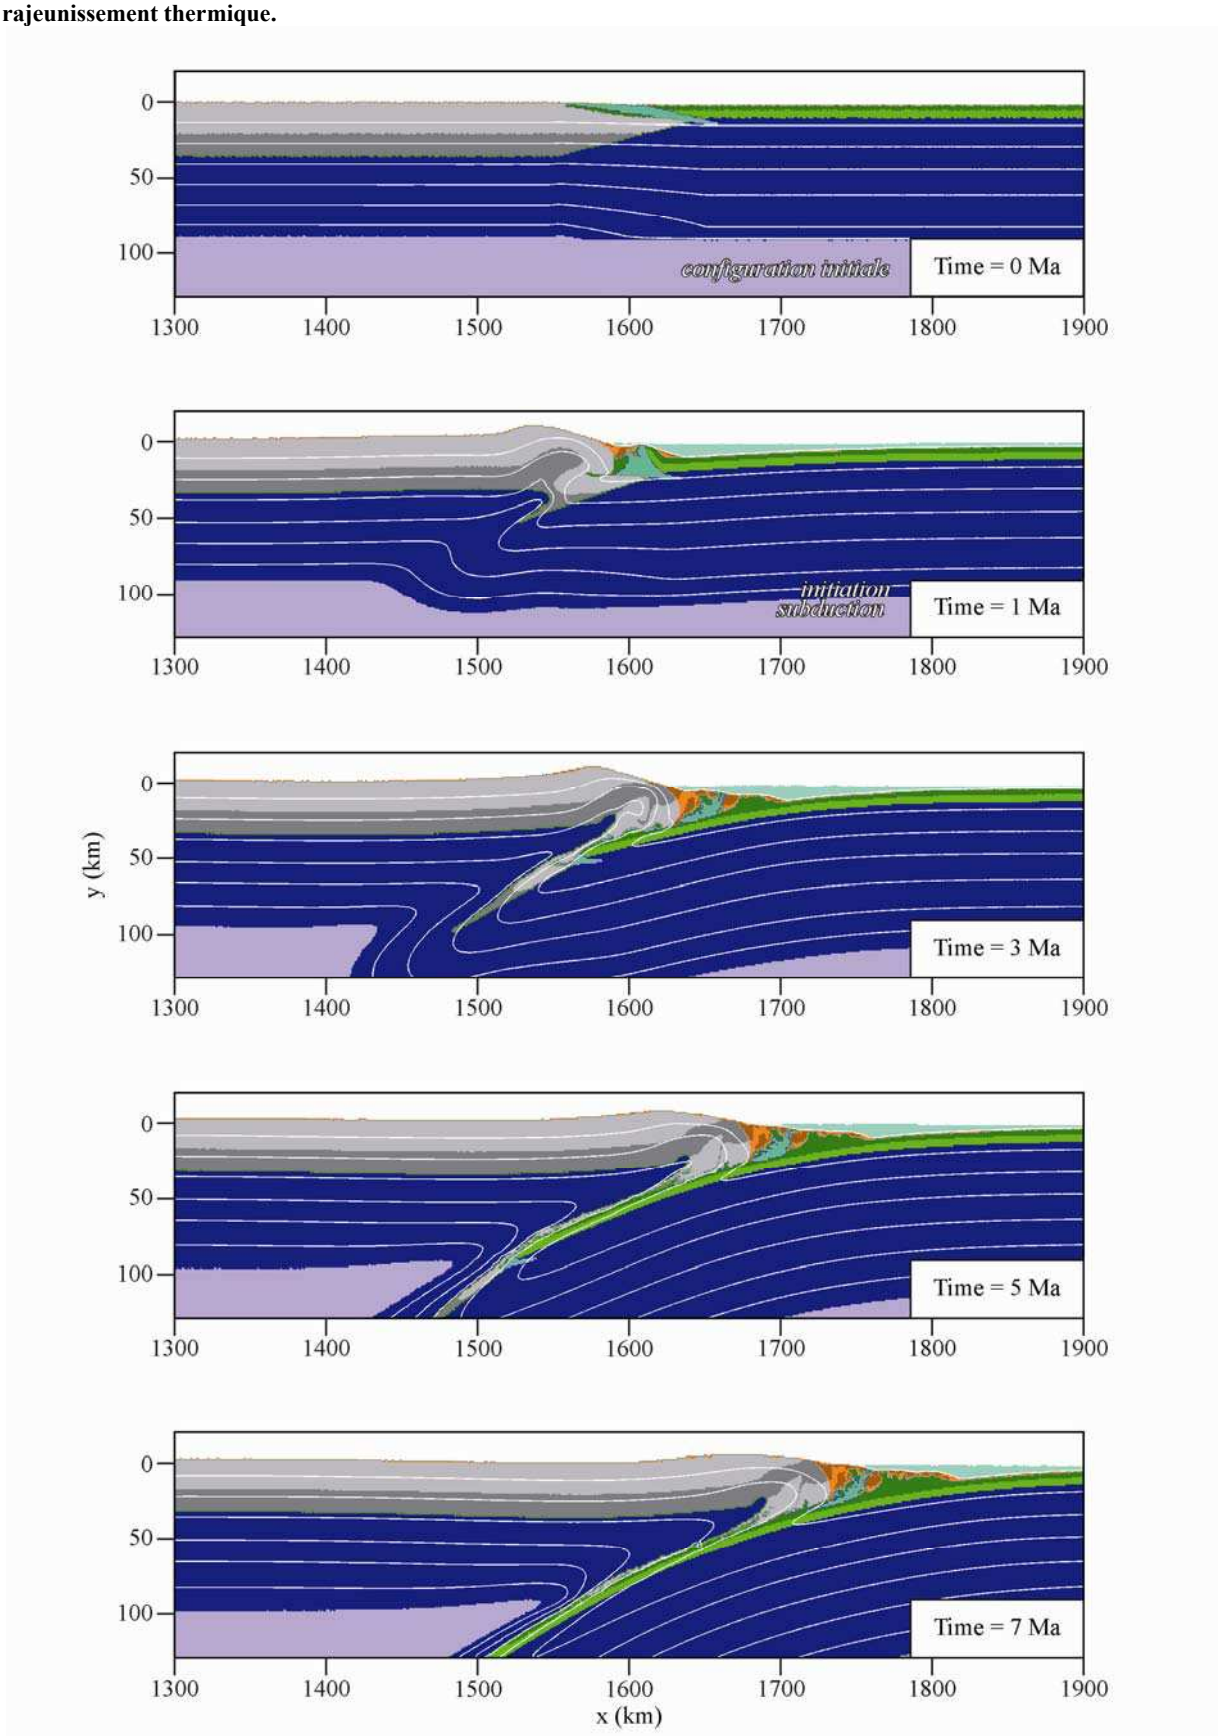
Au cours du retrait de la partie mantellique de la lithosphère océanique préalablement obduite, le bombement du front d'obduction recule au fur et à mesure que la lithosphère se retire mais ne se réduit pas pour autant.

On constant qu'au cours de cette délamination lithosphérique, le chenal de subduction/obduction est également exhumé sous l'effet de la remontée de la croûte continentale. Ces roches métamorphiques se retrouvent ainsi en position basale d'une tranche de lithosphère océanique représentée par de la croûte océanique mais également du manteau lithosphérique. Au regard de cette modélisation, nous suggérons que la complémentarité ou non des différents régimes d'obduction (cf **Figure 6**) est dû à l'état thermique de l'ophiolite.

2.4 Modèle 3 – sans rajeunissement thermique du domaine océanique

L'évolution de ce modèle peut seulement être abordée en une seule étape (**Figure 64**). Avec cette modélisation nous avons mis en évidence l'importance d'un état thermique anormalement élevé de la lithosphère océanique pour générer une obduction. Nous pouvons constater que malgré une pré-structuration favorable au chevauchement de la lithosphère continentale par de la lithosphère océanique, la densité plus élevé du domaine océanique conduit à la formation d'une subduction. Nous ne nous attarderons pas sur ce modèle car les modalités des premières étapes de la genèse d'une zone de subduction ne sont pas l'objet de ce travail et sont encore largement débattus.

Figure 64 - Evolution temporelle du modèle 3 caractérisé par une lithosphère océanique vieille n'ayant pas subi de rajeunissement thermique.



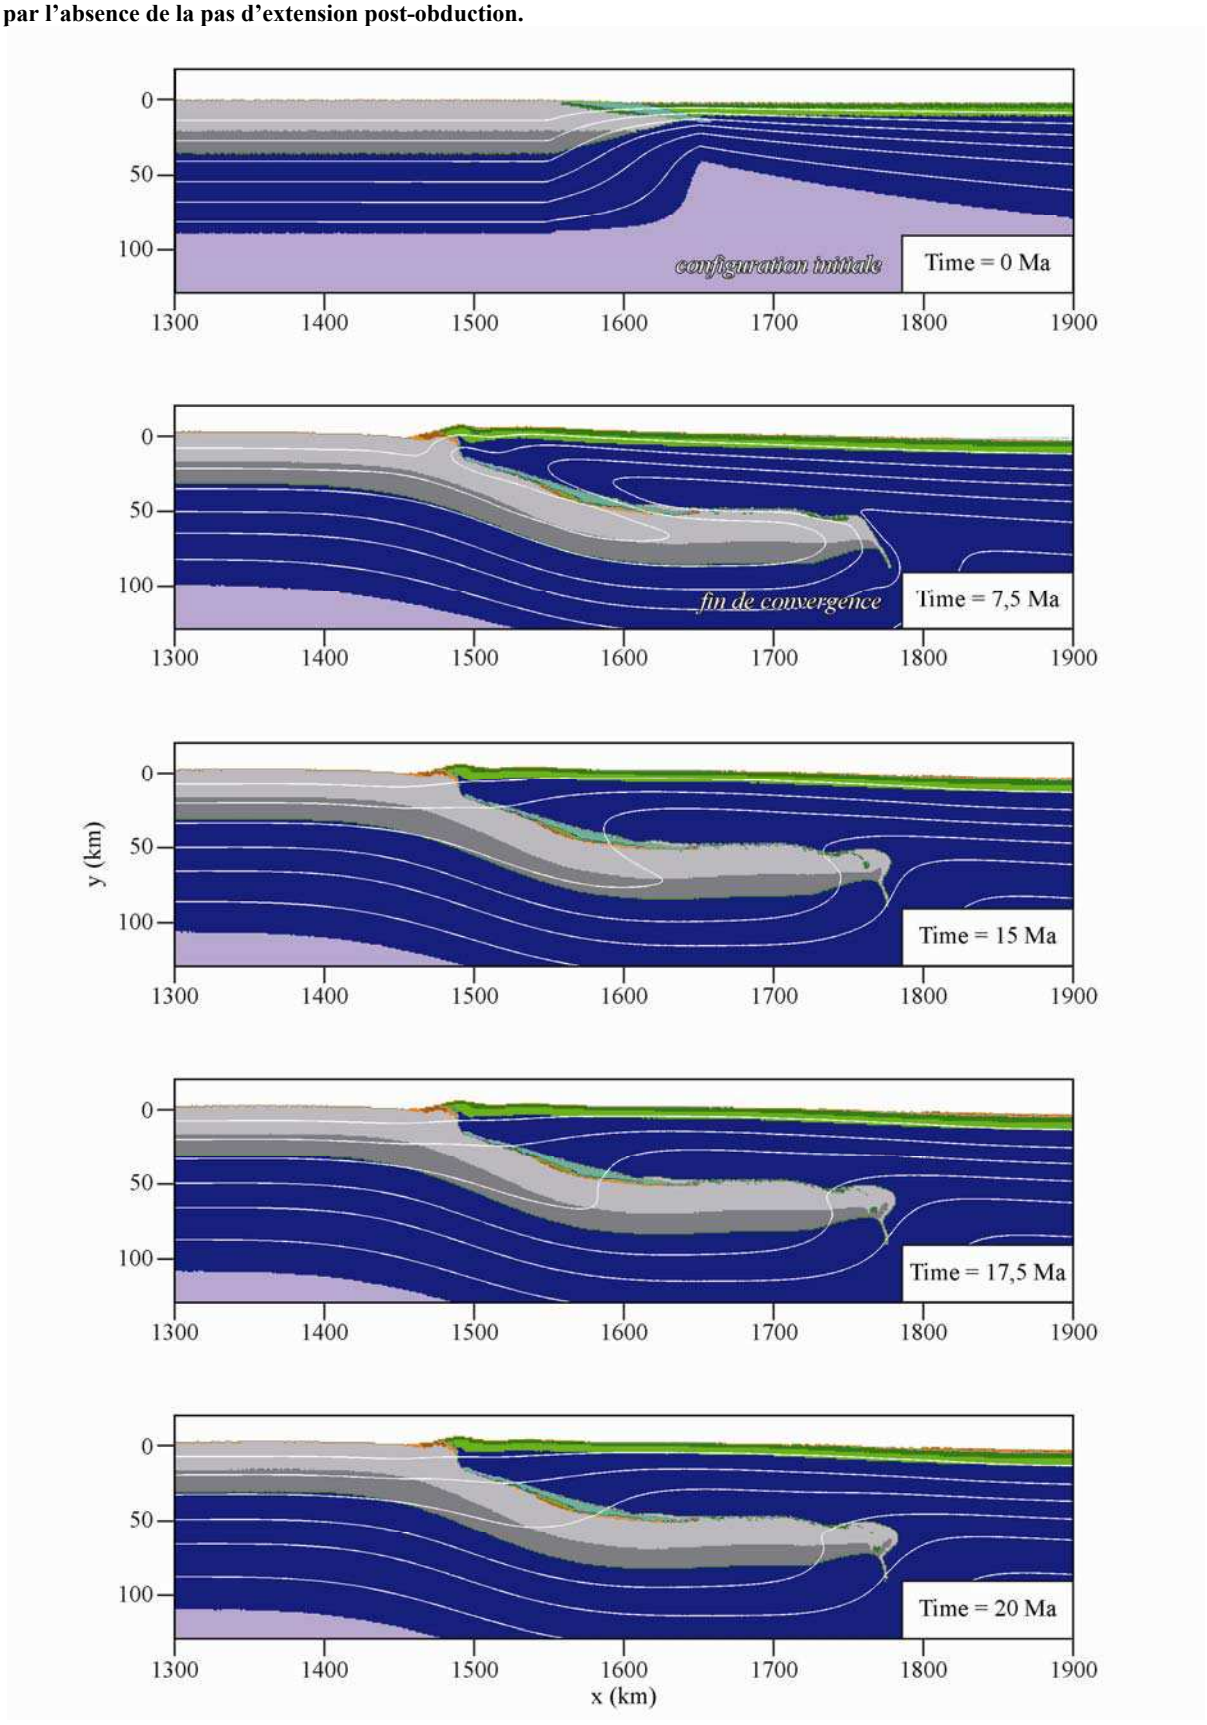
2.5 Modèle 4 – sans extension post-obduction

Tout comme la modélisation précédente l'évolution de ce modèle peut seulement être abordée en étape (**Figure 65**) puisqu'il n'y a pas d'extension imposé. Nous constatons que la flottabilité positive de la croûte continentale ne peut être seule responsable de l'extraction du manteau lithosphérique du domaine océanique.

Tout comme dans la deuxième modélisation, au cours de la convergence de deux domaines les contraintes s'accumulent progressivement. A 5 Ma la marge continentale en subduction atteint une profondeur à laquelle la flottabilité positive de sa croûte provoque une réduction de l'angle de plongement. A 6 Ma la subduction de la marge continentale progresse en une subduction plate avec un angle de plongement faible. La marge continentale est enfouie à une profondeur maximum de 70 km. A 7,5 Ma, les 500 km de convergence sont atteints. Le stade subduction continentale/obduction s'arrête. Une épaisseur importante de lithosphère océanique a été charriée et mise en place (~50 km) composé de plus de 40 km de manteau lithosphérique.

Sans extension imposée, il n'y a pas de traction de la partie mantellique de la lithosphère océanique. On constate que le modèle n'évolue plus.

Figure 65 - Evolution temporelle du modèle 2 caractérisé par une lithosphère océanique vieille mais d'un âge thermique de 5 Ma sur restreint à un domaine proche de la marge continentale. Ce modèle ce distingue du modèle 2 par l'absence de la pas d'extension post-obduction.



VI.3 Discussion de la modélisation

Nous testons quatre scénarios pour la mise en place d'une nappe ophiolitique. Il apparait qu'il est nécessaire d'avoir un domaine océanique relativement jeune (âge thermique de 5 Ma) pour initier une obduction le long d'une marge passive. Dans ces scénario une marge passive continentale présente une TOC marquée par un niveau de découplage possible (serpentinites) avec une lithosphère océanique. En plus du niveau de découplage à la TOC, un état thermique anormalement élevé de la lithosphère océanique est nécessaire (modèles 1 et 2). Afin d'obtenir des résultats proches des observations de terrain et des modèles conceptuels qui en découlent, il est aussi indispensable d'incorporer une phase d'extension suite à la phase compressive de subduction continentale/obduction.

Conclusions Générale

« Ecrire c'est ébranler le sens du monde, y disposer une interrogation indirecte, à laquelle l'écrivain, par un dernier suspens, s'abstient de répondre. La réponse, c'est chacun de nous qui la donne, y apportant son histoire, son langage, sa liberté. »

Roland Barthesne

Conclusion Générale

L'étude pluridisciplinaire des ophiolites du Petit Caucase et de NE Anatolie ainsi que les modélisations qui en découlent nous ont permit de préciser l'évolution des premiers stades de la fermeture néotéthysienne et en conséquence l'obduction de ces dernières, tels que :

(1) L'âge des formations sédimentaires sur les ophiolites en front est identique aux âges des sédiments remobilisés se trouvant dans l'olistrostrome. Ces âges permettent de contraindre le début du processus d'obduction. Ils sont dans la marge d'erreur des âges radiométriques obtenus pour les roches métamorphiques de la semelle d'obduction des ophiolites le long de la suture. Les ophiolites sont peu déformées et présentent une structure préservée.

(2) Les roches du socle cristallin du SAB ne présentent pas de lithologies de haute pression.

(3) En arrière de l'obduction un bassin océanique subsiste après la mise en place des ophiolites. L'extension imposée dans le modèle après 500 km de convergence représente la traction en subduction sous l'Eurasie de la lithosphère océanique.

(4) Remarquons que l'activité volcanique de la marge Eurasienne présente une période de quiescence pendant la période de mise en place des ophiolites. Ceci témoigne vraisemblablement d'une période de faible activité de la subduction à l'origine de ce volcanisme. La compression imposée pour faire converger les domaines lithosphériques a apparemment comme origine un saut de contraintes vers le sud. Ce saut de contraintes contrebalancerait le blocage/ralentissement de la subduction sous l'Eurasie. Ainsi dans un cadre globale, l'obduction compense le blocage/ralentissement la subduction en accommodant le raccourcissement en surface.

(5) Les conditions thermiques sont d'une importance capitale, et même nécessaire, car l'état thermique de la croûte océanique anormalement élevée permet de faire chevaucher un domaine de roches dense sur un domaine de roche moins dense sur de grandes distances.

L'obduction apparaît ainsi tout à la fois singulière et ordinaire, puisqu'elle semble dériver d'un système de type subduction, l'un des processus les plus spécifiques du globe (Stern, 2004; Agard et al., 2007). Dans le cas de la mise en place des ophiolites de la branche nord de la Néotéthys, elle constitue un processus géodynamique à part entière. Même si son occurrence semble appartenir à une étape bien particulière de la phase de convergence d'un cycle de type Wilson, elle ne correspond pas uniquement à la terminaison du cycle subduction

(subduction continentale). Elle est caractérisée par un ensemble de conditions propres, qui sont diffèrents de ce ceux de la subduction.

- Le cas du Petit Caucase montre qu'il est possible de déclencher l'obduction d'une croûte océanique même vieille, et même s'il reste un domaine océanique important à faire disparaitre. Pis, le déclenchement de plusieurs obductions simultanées sur plusieurs marges continentales distinctes le long d'un même transect, est en contradiction avec le principe d'une continuité entre subduction et obduction : il s'agit de deux mécanismes distincts. L'un prenant le relais de l'autre. Dans le cas du Caucase, le blocage de la subduction nord a sans doute joué un rôle déclencheur sur l'obduction.
- Notre étude montre qu'il faut prendre en compte l'état thermique du domaine océanique obducté. En effet les modélisations tendent à démontrer que le rajeunissement thermique est primordial dans le cas d'ophiolites vieilles comme le montre notre étude.
- La progression d'une obduction sur une grande distance pourrait s'expliquer par la reprise de la subduction sur l'une des limites du système (autrement dit, conduisant au retrait, et à l'aminicissement de la lithosphère obduite). La vitesse de la subduction (traction de la plaque plongeante) va alors jouer un rôle important sur l'extension et l'amincissement des ophiolites obduites.

Annexe 1 - Méthodes analytiques

1 - EMPA

L'analyse d'un échantillon par Sonde Electronique (Electron Probe Micro Analysis) permet de déterminer sa composition. Elle s'appuie sur la mesure de l'intensité du rayonnement X caractéristique émis par un élément donné, dans des conditions particulières d'excitation.

Raymond Castaing a été le premier à établir les bases physiques de l'analyse quantitative en démontrant l'existence d'une relation entre cette intensité et la concentration de l'élément correspondant (Castaing, 1951). Au cours des 40 dernières années, la microanalyse a largement évolué. Si les bases physiques posées par Castaing sont sensiblement les mêmes, nous avons maintenant à notre disposition des moyens de calcul performants grâce au développement des calculateurs. Les différents modèles développés depuis ont permis d'affiner les effets de ralentissement et de rétrodiffusion des électrons, l'absorption et la fluorescence.

Les modèles les plus récents s'appliquent à des situations de plus en plus complexes et il est désormais possible de quantifier des éléments difficiles à mesurer tels que les éléments légers, des structures complexes telles les couches minces et les échantillons stratifiés. L'augmentation de la puissance des calculateurs associée à l'amélioration des algorithmes de calcul, permet, entre autres, le traitement des images quantitatives en temps réel et l'optimisation de la mesure par simulation analytique.

Appareillage

Une microsonde électronique (**Figure A1**), comme un microscope électronique à balayage, est constituée d'un canon à électrons, d'une colonne électronique destinée à réduire le diamètre de la sonde électronique au niveau de l'échantillon, d'un dispositif interne de balayage du faisceau électronique, de détecteurs pour le rayonnement X, éventuellement d'autres détecteurs (électrons, photons visibles), et aussi d'un microscope optique.

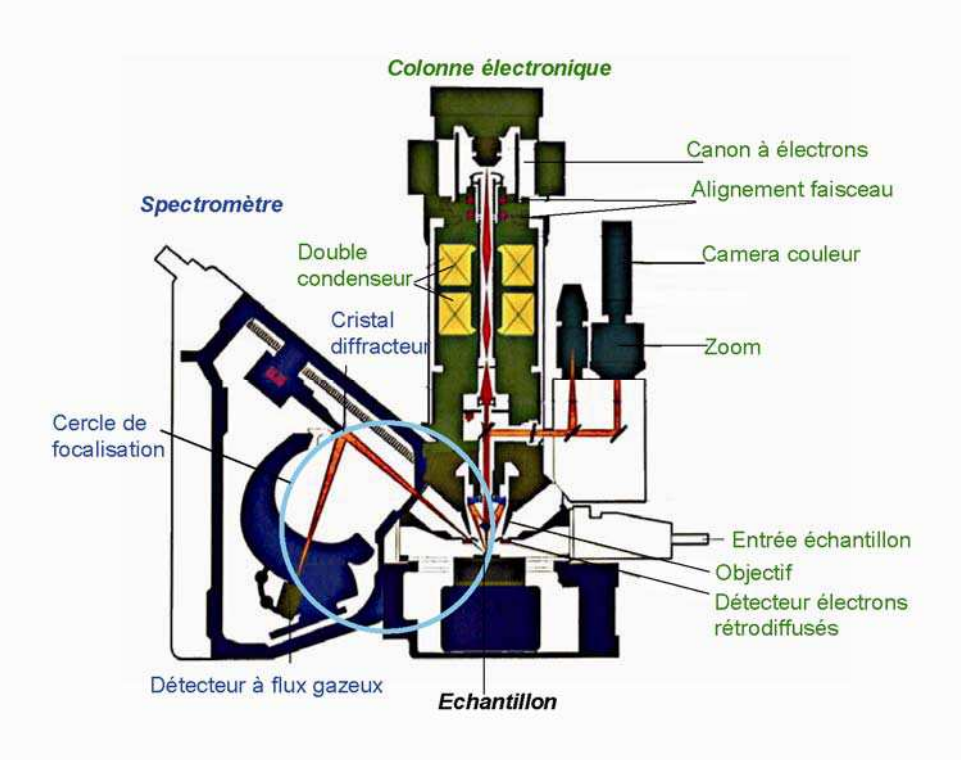

Figure 66 - Schéma des composants d'une microsonde éléctronique.

Le canon à électrons utilise le plus souvent l'effet thermoélectronique, ce qui correspond tout simplement à un fil de tungstène en pointe (le filament) qui est chauffé par effet Joule à une température de 2700 K. Les électrons émis par le filament sont accélérés par le champ électrique qui règne entre le filament (polarisé négativement) et l'anode reliée à la masse. Ce champ électrique correspond à la tension d'accélération des électrons.

La colonne électronique est constituée de plusieurs lentilles électromagnétiques, dont le but est à la fois d'obtenir sur l'échantillon un faisceau focalisé de faible diamètre et d'ajuster l'intensité du faisceau primaire en fonction des besoins.

Mode d'utilisation

Si à l'origine, la microanalyse a été développée dans le but essentiel de fournir une information quantitative ponctuelle, l'aspect « imagerie » a pris une importance de plus en plus grande.

-mode ponctuel. En positionnant à l'aide du microscope électronique à balayage ou du microscope optique la sonde sur la phase à analyser, on peut obtenir la composition élémentaire dans un volume de l'ordre du micron cube.

-mode " traversée " ou " profil ". En déplaçant linéairement le faisceau électronique, ou l'échantillon, et en mesurant la variation de l'émission X d'un élément donné, on obtient

un profil de concentration correspondant. Ce mode d'utilisation est en général qualitatif. Ce mode peut être quantitatif, mais nécessite un échantillon parfaitement poli sur tout le trajet du déplacement.

-mode image. C'est le mode habituel du microscope électronique à balayage. On peut ainsi obtenir l'image de la distribution des éléments de l'échantillon. Ce mode peut être qualitatif, ou quantitatif et visualisé en pseudo couleurs.

Analyse qualitative

La mesure d'un spectre permet de préciser la nature des éléments. L'intensité des raies donne une estimation de la concentration.

Analyse quantitative

Nécessite des conditions de préparation d'échantillon et des conditions opératoires draconiennes.

-échantillon massifs. La microanalyse par sonde électronique est capable de quantifier avec une incertitude de l'ordre du % ou mieux les échantillons massifs.

-échantillon stratifiés. Il est possible également de quantifier les différentes couches d'un échantillon composé de matériaux différents. La profondeur maximale analysée sera de l'ordre d'une dizaine de microns. Des couches d'une épaisseur monoatomique peuvent être quantifiées en concentration et en épaisseur.

Conditions opératoires

-Choix de la tension d'accélération. Cette tension d'accélération (HT) devra être choisie de manière à exciter tous les éléments de l'échantillon. Le volume analysé est proportionnel à la tension d'accélération, et en première approximation le volume excité double tous les 5 keV. L'intensité émise sera également proportionnelle à cette tension. Très grossièrement si le volume double, l'intensité mesurée double. On augmente la sensibilité en augmentant la HT, mais on perd en résolution spatiale.

-Choix de l'intensité du faisceau électronique. L'intensité du faisceau électronique doit être suffisante pour que le signal X soit statistiquement significatif. Quand on augmente l'intensité électronique, le diamètre de la sonde augmente, on a donc une perte de résolution

(faible comparée à la HT). On ne peut augmenter indéfiniment l'intensité du faisceau électronique, car il y aura destruction de l'échantillon.

Préparation de l'échantillon

Pour l'analyse quantitative il est nécessaire d'avoir un échantillon poli optiquement. Une surface rugueuse au sens microscopique (c'est-à-dire des défauts de planéité de l'ordre du micron) entraîne des modifications importantes de l'émission X primaire et donc des concentrations calculées. Pour les échantillons isolants il est nécessaire d'effectuer une faible métallisation de surface, afin d'établir la continuité électrique entre l'échantillon et la masse de l'appareil (le faisceau électronique étant un courant électrique).

Il est nécessaire de respecter les conditions suivantes de préparations d'échantillons afin d'avoir des échantillons uniformes et de bonnes qualités. Le premier critère de qualité sur les résultats est la préparation de l'échantillon (90% des incertitudes sur les résultats proviennent de l'état de surface de l'échantillon). Les surfaces doivent être planes, polies optiquement (0.1micron) et parfaitement propres. Pour les matériaux non conducteurs, une métallisation avec une couche de carbone (250 ± 20 Å d'épaisseur) est effectuée (la qualité de la couche déposée est dépendante de la propreté des surfaces).

Il est important de noter que les problèmes liés à la préparation des échantillons et à leur contamination sont une des sources majeures d'incertitude de l'analyse par sonde électronique.

Il est nécessaire de faire une étude optique préliminaire et poussée de son échantillon utilisant une lumière réfléchie et transmise sur les mêmes sections polies et lames mince que celles prévues pour analyses. Cette étude permet outre l'étude structurale des échantillons, de choisir dans un premier temps les échantillons les mieux adaptés au problème.

2 - ICPMS

La spectrométrie de masse est une technique instrumentale d'analyse reposant sur la séparation, la qualification mais surtout la quantification des éléments chimiques qui constituent un échantillon en fonction de leur masse. Elle est basée sur le couplage d'une torche à plasma générant des ions et d'un spectromètre de masse quadripolaire qui sépare ces ions en masse. Cette technique permet de déterminer la composition chimique d'un échantillon ainsi que mesurer des concentrations d'éléments très faible.

Suite au broyage de l'échantillon (broyeur agate), l'analyse des échantillons par ICP-MS se divise en quatre parties : introduction-nébulisation, ionisation, séparation en masse, détection.

L'échantillon est mis en solution. Un passeur automatique d'échantillons couplé à une pompe péristaltique introduit la solution dans une chambre de vaporisation où le nébuliseur la transforme en un aérosol liquide composé de micro-gouttelettes de quelques micromètres à l'aide d'argon gazeux. L'aérosol ainsi formé est envoyé dans une torche à plasma d'argon à très haute température (entre 6.000 et 10.000 °C) pour vaporiser, dissocier, atomiser et ioniser la plupart des éléments.

Une partie de ce plasma (10%) est échantillonnée par un premier orifice de 1 mm de diamètre environ au sommet d'un cône en nickel ou en platine appelé « le sampler ». Sous l'effet du vide modéré (1~2 mbar) qui règne dans une chambre de pompage différentiel, qui permet de passer de la pression atmosphérique au vide secondaire du spectromètre de masse, le plasma se détend et passe ensuite dans un deuxième orifice, « le skimmer ». Un système de vide différentiel accélère les ions du plasma vers un ensemble de lentilles électrostatiques qui extrait les ions chargés positivement et les transporte vers un filtre de masse quadripôlaire. Cet ensemble de lentilles est aussi appelé lentille ionique.

Ce filtre de masse permets la transmission de seulement les ions présentant un rapport masse sur charge particulier, déterminé en fonction de la fréquence appliquée au quadripôle. Le principe du spectromètre est basé sur la séparation des éléments en fonction de leur charge et de leur masse. Le spectromètre est composé de quatre barres cylindriques qui sont séparées en deux paires opposées, soumises à un courant continu (DC) et alternatif (RF). Les deux paires de cylindres ont des tensions continues opposées et alternatives de même amplitude mais de signe opposé. Dans le plan formé par la paire de barres positive les ions légers sont trop déviés et heurtent les barres. L'ion à analyser et ceux ayant une masse supérieure restent entre les deux barres. Dans ce plan le quadripôle joue le rôle de filtre passe-haut. Dans le plan

de la paire de barres négative, ce sont les ions lourds qui sont déviés, ce qui équivaut à un filtre passe-bas. En combinant ces deux filtres, seuls les ions ayant le rapport masse/charge désiré seront transmis au détecteur (**Figure A2**).

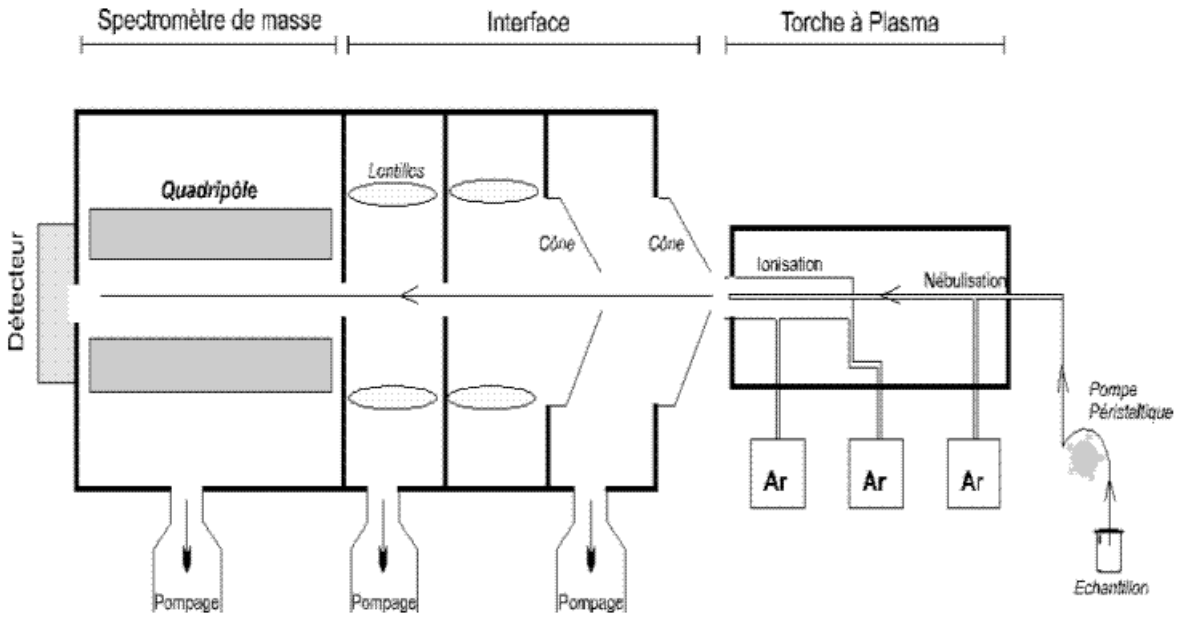

Figure 67 – Schéma conceptuel du spectromètre de masse ICP-MS.

La détection s'effectue grâce à un multiplicateur d'électrons. Pour un isotope donné, le nombre d'ions mesuré permet de calculer directement la concentration de l'élément analysé grâce à un logiciel de traitement quantitatif et qualitatif de l'enregistrement. Les nombres d'électrons sont convertis en concentrations grâce à l'utilisation de deux types de calibrations : externe (solutions étalon) et interne (spikes). Pour les roches, les matrices sont complexes et un traitement supplémentaire des données est nécessaire.

L'ICP-MS est utilisé pour l'analyse simultanée des éléments en trace et « ultra-traces » (teneur est inférieure à 10^{-6} g/g) et pour la détermination des rapports isotopiques dans les roches. Cette technique est d'une excellente sensibilité permettant de détecter des éléments présents au niveau du ppt dans une solution de roche. Sans aucune séparation chimique, il permet l'analyse de nombreux éléments en trace au niveau du ppb (10^{-9} g/g). La précision varie d'un élément à l'autre en fonction du potentiel d'ionisation et des matrices étudiées, l'incertitude moyenne étant inférieure à 3 %.

3 - Géochronologie

Les méthodes de datation utilisées, afin d'obtenir des contraintes géochronologique dans le cadre de ce travail, ont nécessité avant tout une phase d'observation microscopique afin de caractériser les phases minérales présentes. Cette étape d'identification a été suivie d'analyses chimiques afin de déterminer les particularités ainsi que l'adéquation de ces minéraux pour les méthodes envisagées. Ces phases de caractérisation ont été réalisées sur des lames minces polis.

S'en est suivie des opérations de séparation minéralogique afin d'extraire et isoler des monocristaux d'amphibole, mica blanc, biotite et zircon pour datation utilisant les méthodes $^{40}Ar/^{39}Ar$ et U-Pb.

Caractéristiques minérales

Les minéraux qui sont datable par les deux méthodes ont des caractéristiques particulières permettant de les isolées (**Tableau A1**).

Nom	Formule	Classe	Densité	Susceptibilité magnétique
Hornblende	$Ca_2(Mg,Fe,Al)_5(AlSi)_8O_{22}(OH)_2$	Silicate	$2,9 < \rho < 3,4$	$0,1A < \chi_m < 0.8A$
Muscovite	$KAl_2(AlSi_3O_{10})(F,OH)_2$	Silicate	$\rho \sim 2,8$	Non magnétique
Biotite	$K(Fe,Mg)_3AlSiO_{10}(F,OH)_2$	Silicate	$2,9 < \rho < 3,4$	$0,3A < \chi_m < 0,5A$
Zircon	$ZiSiO_2$	Silicate	$4,6 < \rho < 4,7$	Non magnétique

Tableau 19 – Récapitulatif des minéraux utilisés pour datation avec les méthodes $^{40}Ar/^{39}Ar$ et U-Pb.

Protocole de séparation des minéraux

Il existe une série d'étapes afin de correctement isoler les minéraux pouvant être datés pour chaque méthode (**Figure A3**).

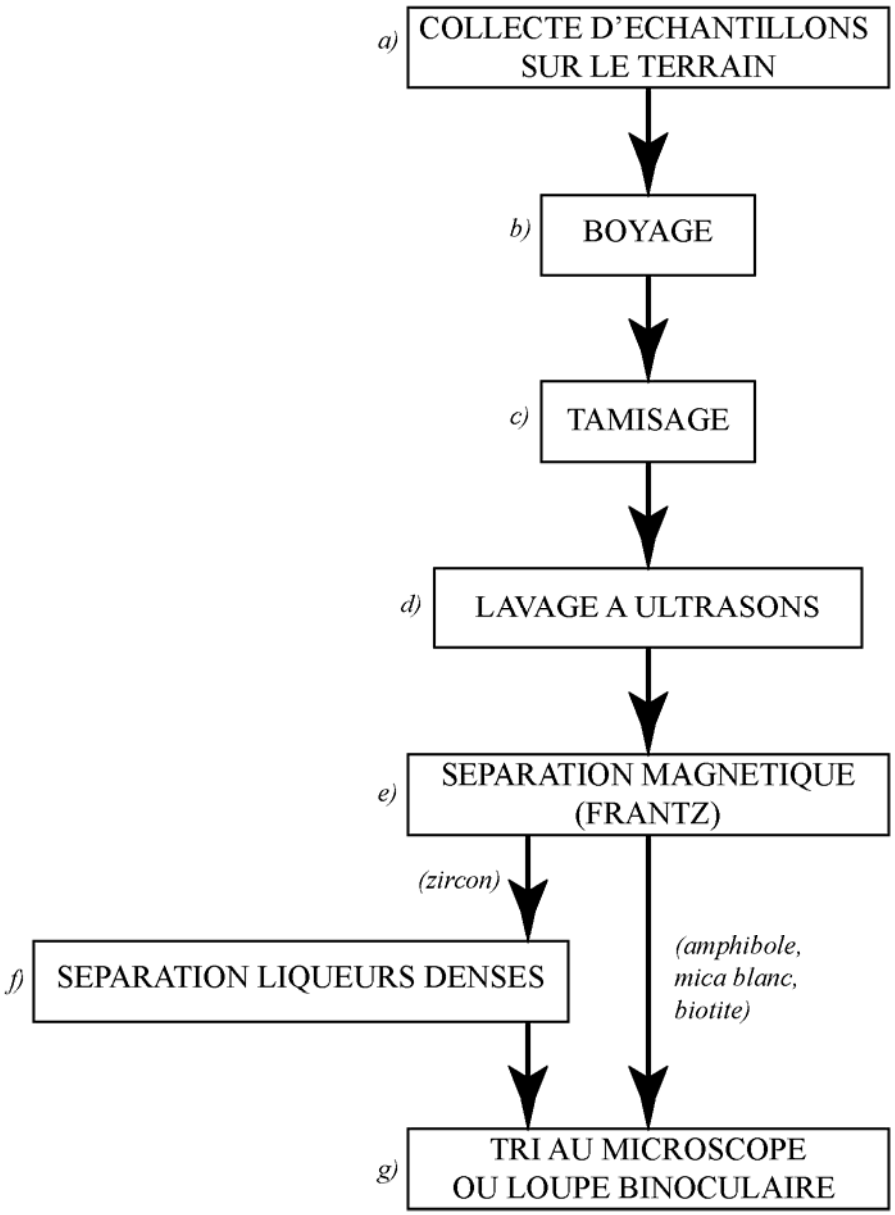

Figure 68 - Etapes successives de séparation minérales.

- Commentaires :
  a) Les échantillons sont prélevés à partir d'affleurements sains et préservés afin d'assurer la qualité des minéraux datés. Ceci est particulièrement important pour la datation $^{40}Ar/^{39}Ar$ car des minéraux altérés, tel que la biotite chloritisé, sont susceptible de présenter des pertes en argon.
  b) Le broyage s'effectue avec un broyeur à mâchoires (larges puis plus petites) pour réduire la taille des morceaux de l'échantillon avant l'utilisation d'un broyeur à disques rotatif. Le but de cette étape est de réduire l'échantillon en poudre.
  c) Le tamisage est réalisé dans le but de récupérer différentes fractions granulométrique des échantillons réduits en poudre. Il se fait une tamiseuse à vibration utilisant des tamis de 200mm de diamètre ayant des mailles de 300µm, 200µm et 100µm.
  d) Les fractions obtenues sont lavées avec de l'eau. Elles sont également agités par ultrasons pour nettoyer les grains de poussières fines et de particules jugées trop petites.
  e) Les trois fractions ainsi lavées sont ensuite passé dans un dispositif à séparation magnétique de type Frantz (**Figure A4**). Pour la datation $^{40}Ar/^{39}Ar$, ceci ne sert qu'à réduire la fraction à trier en séparant les minéraux magnétiques (fraction contenant les hornblendes et biotites) des minéraux non-magnétiques (contenant les micas blancs). Pour la datation U-Pb, trois passages sont effectués. Le premier sert à éliminer les minéraux les plus magnétiques avec des régales de champ de 0.5A, de pente de 8° et de contrepente de 6°. Les minéraux les moins magnétiques sont récupérés pour le deuxième passage avec des réglages de champ de 1.5A, de même pente 8° et de contrepente de 3°. Les minéraux les moins magnétiques sont encore une fois récupérés pour le troisième passage avec des réglages de champ de 1.5A, de pente 8° et de contrepente de 2°. Les meilleurs minéraux pour datation U-Pb seront les derniers non magnétiques (contenant les zircons).
  f) Pour datation U-Pb, les fractions non-magnétiques obtenues sont passés dans une solution de liqueur dense (**Figure A5**). Les minéraux plus denses que la solution (dont les zircons) la traversent alors que les minéraux moins denses sont retenus.
  g) Pour les deux méthodes de datation une étape de tri à la main au microscope ou loupe binoculaire s'en suit afin de sélectionner les plus beau grains (grains uniques, sans inclusions visible et de forme le moins arrondis).

La méthode ^{39}Ar-^{40}Ar

Afin de replacer dans un calendrier tectonique la formation ainsi que les variations de conditions en termes de pression et température des roches étudiées, la méthode 40Ar/39Ar sur des amphiboles, micas blancs et biotites a été utilisée. Ces minéraux ont été extraient de roches magmatiques plutoniques (i.e. gabbros) ainsi que roches métamorphiques (schistes, amphibolites et gneiss) provenant du socle cristallin du Bloc Sud Arménien (SAB), des roches ophiolitique chevauchant le SAB ainsi que des ophiolites de nord-est Anatolie et des roches se trouvant directement sous les ophiolites composant leurs semelle.

Introduction à la technique ^{40}Ar/^{39}Ar

La technique de datation ^{40}Ar/^{39}Ar est la variante la plus communément utilisé de la méthode conventionnelle K-Ar. Elle est basée sur la décomposition naturelle du ^{40}K en ^{40}Ar. La technique repose sur l'idée que l'abondance relative des isotopes du potassium est constante dans les minéraux analysés.

Pour la méthode ^{40}Ar/^{39}Ar l'échantillon à daté est tout d'abord irradié dans un réacteur nucléaire afin de transformer une proportion des atomes ^{39}K en ^{39}Ar suite à l'interaction avec des neutrons rapides. Suite à l'irradiation, l'échantillon est placé dans un système pourvu d'un vide poussé. L'argon est alors extrait par étapes successif de chauffe jusqu'à fusion totale. Après chaque étape de chauffe l'argon extrait est purifié et analysé par un spectromètre de masse isotopique. L'avantage de la méthode est que le rapport entre isotope père (^{40}K) et fils

($^{40}Ar^*$) est mesuré lors de la même analyse, rendant inutile le besoin d'une analyse séparé pour le potassium. Ceci permet de surmonter les problèmes d'inhomogénéité au sain d'un même échantillon et permet, en principe, de dater des échantillons de plus petite taille. En prime, cela permet de mesurer des rapports isotopiques de manière plus précise, réduisant les erreurs analytiques en comparaison à la méthode K-Ar conventionnelle ;

L'avantage majeur de cette technique est quelle s'effectue par étape de chauffe successive à des températures croissantes. L'argon alors extrait à chaque étape peut être analysée isotopiquement donnant une série d'âges apparents pour un échantillon (minéral) donnée. Cette méthode de chauffage, connue comme « chauffage par paliers » ou « chauffage incrémentale » (Merrihue & Turner, 1966), permet d'obtenir un aperçu de la distribution de $^{40}Ar^*$ dans l'échantillon analysé. Cette méthode repose sur le principe de libération d'argon par diffusion thermique au fur et à mesure que l'échantillon est porté à des températures de plus en plus élevé. Au cours des étapes de chauffe, $^{40}Ar^*$ et ^{39}Ar seront libéré en proportion égale dû à leurs coefficient de diffusion proche, donnant un rapport $^{40}Ar^*/^{39}Ar_k$ plus ou moins constant pour chaque fraction de gaz extraite pour chaque palier de chauffe. Un graphique représentant l'âge apparent $^{40}Ar^*/^{39}Ar_k$ pour chaque palier en fonction de la proportion totale d'argon libéré (par convention ^{39}Ar) donnera alors un motif plat, dont on fait référence par le terme de « plateau ». Un spectre d'âge plat, ainsi obtenu, est couramment considérer comme une indication que l'échantillon représente un système fermé. Néanmoins, un échantillon peut perdre une partie de son $^{40}Ar^*$ après cristallisation initiale, suite à un événement métamorphique impliquant un fort réchauffement ou au cours d'exhumation/refroidissement prolongé. Un tel échantillon aura une structure cristalline contenant des sites ayant un rapport $^{40}Ar^*/^{40}K$ différent qui se révéleront lors du chauffage par palier et donneront ainsi un spectre d'âge qui ne sera pas plat.

Idéalement, la méthode $^{40}Ar/^{39}Ar$ permet de définir un âge de refroidissement en relation avec l'exhumation de la roche échantillonné ou l'âge du dernier événement thermique ayant rouvert le système.

Puisque les spectromètres de mass utilisé lors de datations $^{40}Ar/^{39}Ar$ ne mesurent pas habituellement les abondances absolues, des procédures de standardisation ont été adopté afin de calibrer les machines. Un standard couramment utilisé est l'argon atmosphérique. La composition isotopique atmosphérique en argon a été mesurée par Nier (1950) et a permis d'obtenir une valeur de 295.5 pour le rapport $^{40}Ar/^{39}Ar$ tel que stipule Steiger & Jäger (1977). La prise en compte de cette valeur est essentielle afin de mesurer avec succès un âge

$^{40}Ar/^{39}Ar$, des corrections doivent être effectuées pour toute contamination atmosphérique contenue dans l'échantillon ou dans le vide de la ligne d'extraction menant au spectromètre de masse.

Plus de précisions concernant la théorie ainsi que la technique de datation $^{40}Ar/^{39}Ar$, le lecteur est dirigé vers McDougall *&* Harrison (1988).

Dispositif de datation $^{40}Ar/^{39}Ar$ utilisé

Les datations $^{40}Ar/^{39}Ar$ ont été réalisées par paliers de température croissant en utilisant un laser CO2 de 50W Synrad©; les isotopes ont été mesurés en mode statique sur un spectromètre VG3600 équipé d'un système de détection Daly au laboratoire de Géochimie, Géochronologie et Pétrologie de l'UMR7329 Géoazur (**Figure A6**).

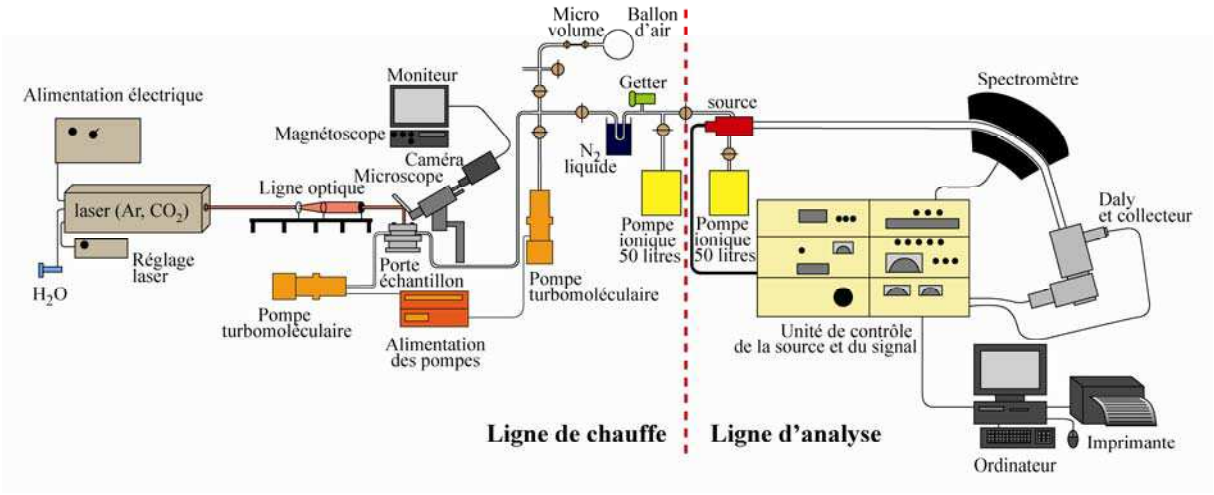

Figure 71 - Schéma du dispositif d'analyse $^{40}Ar/^{39}Ar$.

La méthode U-Pb

Parmi les différents couples radiométriques utilisés en géologie, le système U-Pb est probablement l'un des plus employé. Un des principaux avantages de ce système réside dans le fait qu'il associe deux isotopes pères d'un même élément (^{235}U et ^{238}U) qui se désintègrent suivant des constantes de désintégration différentes pour donner deux isotopes fils d'un autre élément (le ^{207}Pb et le ^{206}Pb respectivement). Ainsi, au cours du temps, la quantité d'uranium décroît régulièrement alors que les quantités de plomb, issues de la désintégration radioactive, augmentent proportionnellement (**Figure A7**). En parallèle et en liaison directe avec le

processus de désintégration radioactive de l'uranium, la composition isotopique du plomb se modifie également, donnant une autre mesure du temps écoulé.

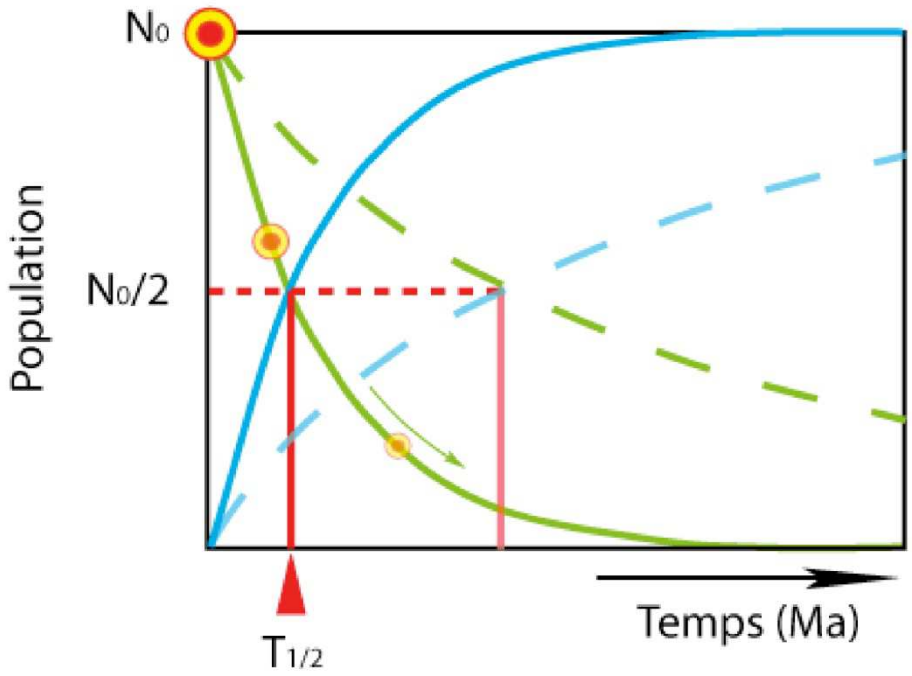

Figure 72 - Graphique représentant la décroissance de la quantité d'uranium et l'augmentation de plomb au cours du temps.

Pour le système U/Pb, cette propriété permet de calculer trois âges à partir de trois rapports isotopiques distincts : deux rapports Pb/U ($^{206}Pb/^{238}U$ et $^{207}Pb/^{235}U$) et un rapport de composition isotopique du plomb ($^{207}Pb/^{206}Pb$). La comparaison entre ces trois âges permet de préciser de façon remarquable si le système U-Pb du minéral considéré est resté clos ou s'il a évolué en système ouvert. Au contraire des autres méthodes utilisées en géochronologie, la méthode U-Pb offre l'avantage, même si le radiochronomètre a évolué en système ouvert, de pouvoir donner une bonne indication de l'âge. Ainsi, il est parfois possible de retrouver non seulement l'âge initial du système mais également celui de son ouverture. Cette combinaison unique de deux chronomètres naturels a été très tôt exploitée par Wetherill (1956) dans le diagramme "concordia" (**Figure A8**).

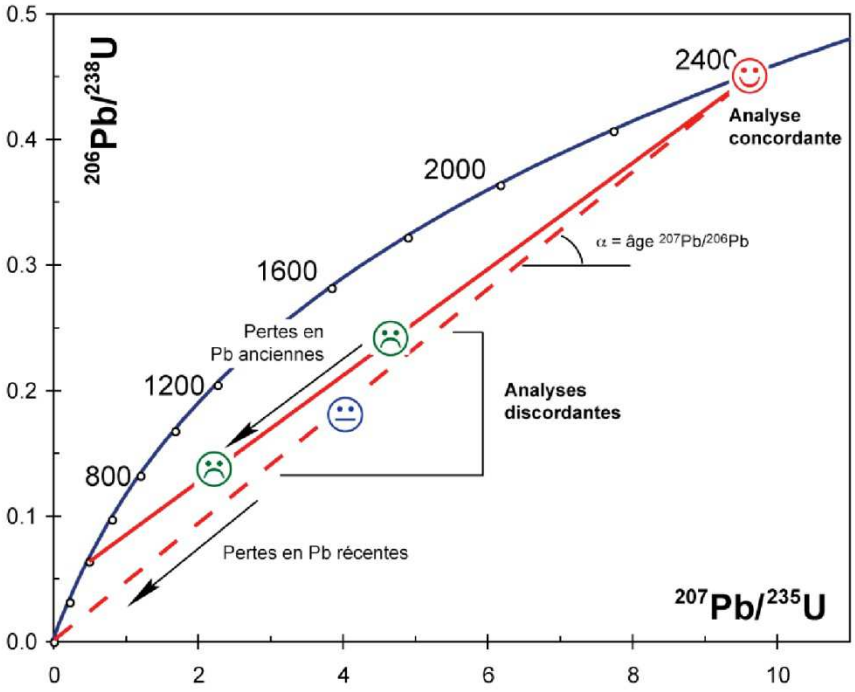

Figure 73 – Diagramme illustrant le principe d'utilisation de la courbe concordia.

Certains minéraux peuvent intégrer des éléments radioactifs dans leur réseau cristallin soit directement car ils entrent dans la formule chimique du minéral en tant que constituant principal, soit par substitution à un élément principal en raison de similarité de taille et de charge dans la majorité des cas (exp. substitution de l'U^{4+} au Zr^{4+} dans le réseau cristallin du zircon; **Figure A9**). Les minéraux les plus intéressants en géochronologique U-Pb sont ceux qui, lors de leur cristallisation, intègrent dans leur réseau cristallin une quantité notable d'éléments radioactifs pères (U), tout en excluant l'intégration de Pb commun.

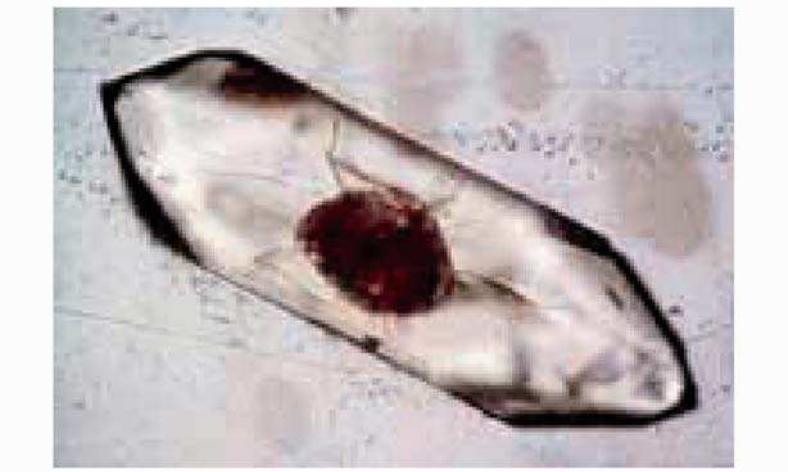

Figure 74 – Cristal de zircon presentant une inclusion.

Ainsi, la totalité des éléments fils présents dans ces minéraux à un instant t est d'origine radiogénique. Ceci est à opposer à d'autres minéraux qui, en plus des isotopes pères, intègrent dans leur réseau, au moment de leur cristallisation, des quantités non négligeables d'élément correspondant à l'isotope fils (substitution de Ca^{2+} par Pb^{2+} par exemple dans le cas de l'apatite). La présence de ces isotopes fils, non radiogéniques, dans le système dès la cristallisation du minéral nécessite une correction, qui dans le cas du système U-Pb pourra être réalisée grâce à l'analyse de phases minérales à rapport U/Pb très faible (feldspath, galène…) ou par estimation grâce à des modèles d'évolution de la composition isotopique en Pb en milieu crustal (Stacey & Kramers, 1975; Cumming & Richards 1975).

Introduction à la technique U-Pb

L'analyse U-Pb par voie ponctuelle permet d'étudier des portions de grains, sans manipulation chimique préalable, et ce, en utilisant un faisceau ionique capable d'éroder progressivement la surface de l'échantillon puis d'analyser la composition isotopique du nuage d'ions ainsi produits. Bien que, dans un premier temps limitée à l'analyse des rapports $^{207}Pb/^{206}Pb$ (e.g. Andersen 1973), cette technique a rapidement évolué afin de permettre la mesure fiable des rapports Pb/U (Hinthorne *et al.*, 1979). Les progrès analytiques constants, et en particulier l'utilisation de la haute résolution (e.g. Hinton & Long, 1979) pour résoudre les interférences moléculaires observées sur les isotopes du Pb, ont depuis permis d'appliquer avec succès cette technique à la datation d'échantillons d'âges très variés (Froude *et al.*, 1983; Compston & Pidgeon, 1986; Deloule *et al.*, 2001) ou à des phases minérales ayant préservées au niveau de leur structure interne une grande complexité (Black *et al.*, 1986; Williams & Claesson, 1987; Compston & Kröner, 1988; Kinny *et al.*, 1988). Cette technique ne permet pas de distinguer une séquence d'évènements se produisant dans un intervalle de temps limité (< 15 Ma). La méthode est cependant rapide, quasiment non destructrice, et présente une résolution spatiale de quelques dizaines de microns ce qui permet l'analyse individuelle de différentes parties d'un même cristal pouvant correspondre à une croissance polyphasée.

Les sondes ioniques sont donc des appareils de choix pour déterminer l'âge d'échantillons ou de minéraux très complexes. C'est le cas par exemple, de roches polymétamorphiques ou bien pour les études visant à déconvoluer le spectre d'âge des populations de zircons détritiques ou encore celles visant à déterminer, dans les granitoïdes, l'âge des matériaux sources ayant subi le processus de fusion partielle.

4 - Perple_X

La modélisation de l'espace P-T : les pseudosections (PERPLEX)

Traditionnellement, les grilles pétrogénétiques montrent les relations de phases pour toutes les compositions possibles d'un système en fonction de variables environnementales (P,T…). Les champs divariants de stabilité des phases minérales sont ainsi représentés sans tenir compte de la composition de la roche totale. Par conséquent, il devient nécessaire de recalculer des diagrammes de phases représentant fidèlement la composition du système étudié. Ainsi, les sections de diagrammes de phases (ou pseudosections) calculées à partir d'une composition de roche totale définie et une minéralogie observée et chimiquement quantifiée (comme avec le logiciel Perplex) ont offert une alternative aux méthodes classiques de projections de phases.

Théorie et principes

Le principe d'une pseudosection est de modéliser les assemblages minéralogiques à l'équilibre dans l'espace P-T à partir d'une composition chimique d'un volume de roche et des données thermodynamiques disponibles. Les pseudosections calculées pour un système chimique défini préalablement correspondent donc à des portions ou sections de l'espace P-T pour lesquels les paragenèses sont prédites. Les informations thermobarométriques sont extraites grâce à la position dans l'espace P-T des champs de stabilité des minéraux ainsi que par les proportions et les compositions minéralogiques dans ces mêmes champs. Une comparaison avec les paragenèses et les compositions chimiques observées dans les échantillons permet donc une estimation des conditions thermobarométriques de formation de l'association minéralogique (e.g. Vance & Mahar, 1998). L'avantage de cette méthode, hormis l'estimation des conditions P-T, est qu'elle permet la modélisation d'une portion du chemin P-T à partir de l'analyse de l'évolution minéralogique et chimique lors de transformations texturales de la roche. Les pseudosections permettent ainsi de comparer les paragenèses observées avec celles prédites, même celles qui ont pu disparaitre. Pour ces raisons et du fait d'être indépendante de la chimie de la roche, cette méthode se révèle être très avantageuse dans les zones texturellement compliquées, comme c'est le cas ici, où le métamorphisme se localise essentiellement dans des zones de cisaillement.

Construction d'une pseudosection avec Perplex (P-T et T-X ou P-X)

Plusieurs approches dont les modes de calcul d'équilibre diffèrent, ont été développées et largement utilisées par les géologues. Le logiciel utilisé dans la présente étude est le logiciel PERPLEX crée par Connolly & Kerrick (1987). Basé sur le principe de calcul des surfaces d'équilibre où l'énergie libre du système chimique représenté par un assemblage de minéraux est minimale, cette technique permet d'estimer l'équilibre le plus stable pour une composition donnée et ce en tout point de l'espace défini préalablement. Autrement dit, le logiciel calcule, pour tout couple (P-T) les phases minérales stables en minimisant l'énergie libre du système.

Minimisation linéaire de l'énergie libre : simplicité et rapidité

Le problème de la minimisation est de trouver la quantité et la composition des phases qui minimisent l'énergie libre de Gibbs (G) du système chimique à pression et température constante (White *et al.*, 1958 ; De Capitani & Brown, 1987). La fonction d'énergie libre est une fonction non linéaire de la composition ; par conséquent la solution numérique des calculs d'équilibre de phases est compliquée, incertaine et nécessite souvent un temps de calcul important. Connolly et Kerrick en 1987 ont développé une méthode d'approximation par laquelle les variations continues de composition de phases minérales sont représentées par une série de valeurs discrètes de composition telles que chaque composition ont les propriétés thermodynamiques de la solution solide à une composition choisie. L'énergie libre devient donc une fonction linéaire de la composition définie par chaque segment entre les pseudocompositions. La précision de l'approximation est dépendante de l'espacement entre les pseudocompositions; étant donnée les ressources numériques actuelles et l'exactitude des modèles thermodynamiques des phases minérales, ceci ne constitue pas une importante limitation de la méthode.

Stabilité des assemblages de minéraux : une détermination automatisée

Le principe de base de la thermobarométrique est que les assemblages minéralogiques utilisés sont à l'équilibre. Le plus souvent il est nécessaire de connaitre préalablement les différentes phases stables (Powell & Holland, 1988). Le logiciel Perplex présente l'avantage de déterminer et tester de manière automatique la stabilité des associations minérales obtenues lors du calcul d'équilibre sans qu'aucune des phases supposées à l'équilibre ne lui soient

spécifiées (Connolly & Petrini, 2002). Ceci présente un certain avantage en ce qu'il évite une connaissance préalable des minéraux à l'équilibre, notamment, dans le cas où certains minéraux présentent un équilibre métastable.

Stratégie numérique : une résolution à plusieurs niveaux de la grille P-T-X

La technique de minimisation linéaire fournit une carte des équilibres minéralogiques d'un système thermodynamique pour une section de l'espace P-T-X. Les champs de stabilité dans lesquels la composition chimique et les proportions des phases stables varient en continu sont définis en tout point de l'espace. Une stratégie est proposée par Connolly & Kerrick (2002) et Connolly (2005) afin de déterminer directement les relations de phases en fonction de variables environnementales (P, T…). Les auteurs proposent ainsi un protocole de calcul d'équilibre de phase en tout point d'une grille, dont la résolution est définie préalablement par l'utilisateur et présente plusieurs niveaux de définition. Plus simplement, les pseudocompositions stables sont déterminées après 1,2 et 3 passages successifs à chaque nœud du maillage de la grille par minimisation linéaire de la surface d'énergie libre. Au premier passage, si le même assemblage est stable aux sommets d'une cellule alors l'assemblage est considéré comme stable à chaque niveau de résolution de la grille ; si la cellule est hétérogène, un calcul avec une résolution plus fine sera automatiquement effectué lors du deuxième passage.

La conséquence des pseudocompositions est que les variations continues des compositions de phases stables deviennent discontinues ; chaque champ de stabilité de phases d'une section caractérise alors des champs dits « pseudodivariants » dont chacun est défini par une pseudocomposition. Les limites entre les champs « pseudodivariants » représentent ainsi soit une vraie transformation de phase soit une variation de la composition d'une solution solide. Dans le but de représenter uniquement les vraies limites de phases, les pseudocompositions qui représentent les mêmes phases sont considérées comme identiques.

Au final, une carte des relations de phases ou champ de stabilité dont les limites représentent les transformations minérales peut être ainsi construite. Les propriétés telles que la composition chimique et les proportions des phases minérales mémorisées lors de chaque minimisation peuvent être déterminées. Étant donné que ces propriétés varient de manière continue en fonction des variables environnementales, elles sont estimées par interpolation ou extrapolation triangulaires. Cette stratégie de grille à plusieurs niveaux de résolution présente

donc l'avantage d'être simple, rapide puisqu'elle réduit considérablement le nombre de minimisation à calculer et avec un niveau d'efficacité comparable à d'autres techniques.

Il faut néanmoins garder à l'esprit qu'il s'agit d'une solution exacte à un problème qui a été simplifié. Toutefois, la confrontation avec les autres méthodes basées sur le calcul d'équation non linéaire montre que la méthode approximative utilisée par le logiciel PERPLEX est comparable. L'approximation occasionnée par la linéarisation de la fonction d'énergie libre est identique à l'incertitude des modèles thermodynamiques des phases.

Information on Analysis and Constants Used in Calculations

Sample = AR-04-62B
Material = Muscovite
Location = Arménie
Analyst = Yann ROLLAND
Project = ROLLAND_HASSIG
Mass Discrimination Law = LIN
Irradiation = MC45
J = 0.01710430 ± 0.00004276
Hb3gr = 1073.600 ± 5.368 Ma
IGSN = Undefined
Preferred Age = Undefined
Classification = Undefined
Experiment Type = Undefined
Extraction Method = Undefined
Heating = 600 sec
Isolation = 2.00 min
Instrument = FOUR
Lithology = Undefined
Lat-Lon = Undefined - Undefined

Age Equations = Conventional
Negative Intensities = Allowed
Decay Constant 40K = 5.543 ± 0.010 E-10 1/a
Decay Constant 39Ar = 2.940 ± 0.029 E-07 1/h
Decay Constant 37Ar = 8.220 ± 0.010 E-04 1/h
Decay Constant 36Cl = 2.310 ± 0.016 E-06 1/a
Production Ratio 36/38 in Cl = 316.0 ± 15.8
